ABSTRACT

Primary mucinous adenocarcinoma of appendix is extremely a rare tumour. Clinically, these tumours present as appendicitis and very rarely as a mass in right iliac fossa; hence, preoperative recognition of adenocarcinoma is very difficult and is usually diagnosed after histopathological examination of specimen operated for appendicitis. Here we report such a rare case of mucinous adenocarcinoma of appendix in a 49-year-old male presented as appendicitis and underwent emergency appendicectomy.

KEYWORDS

Adenocarcinoma, Appendicitis, Appendix, Appendicectomy.

INTRODUCTION

Malignancy of the appendix is very rare and it is commonly found incidentally in approximately <1% of appendicectomies. Clinically, these tumours present as appendix and very rarely as a mass in the right iliac fossa and intestinal obstruction. Therefore, preoperative recognition of adenocarcinoma is not possible and is usually diagnosed after histopathological examination of specimens after removal of suspected appendicitis.

In our institution, two appendiceal neoplasms have been reported among 2043 appendicectomy specimens in the last two years. One is carcinoid and the other is mucinous adenocarcinoma. We report this case of mucinous adenocarcinoma of the appendix presented with symptoms of acute appendicitis.

CASE REPORT

A 49-year-old male presented to our emergency department with complaints of right lower abdominal pain for three days associated with low-grade fever. On examination, he had tenderness in Right Iliac Fossa (RIF). Severe probe tenderness was elicited on ultrasonographic examination. With a probable diagnosis of acute appendicitis, emergency laparotomy was done on the same day. Preoperatively, appendix was seen adherent with the posterior abdominal wall and ileum. Appendicectomy was done. Grossly, appendix specimen measured 5 cm length, external surface was covered with exudate, and cut section showed thickened appendiceal wall with focal mucinous areas and the lumen was occluded. Microscopic examination section showed appendiceal mucosa with ulceration and a neoplasm arranged predominantly in submucosa and muscularis propria composed of glands and clusters of tumour cells. The cells are round to polyhedral with intracytoplasmic mucin and pleomorphic dark-staining nuclei. The neoplasm was seen to infiltrate through the muscularis propria into the serosa.

Evacuated mucin was also made out. The entire appendiceal wall showed acute inflammatory cell infiltrate. In Immunohistochemistry (IHC), the tumour cells showed diffuse strong cytoplasmic positivity for Cytokeratin 20 (CK20).

**Fig. A.** Cut Surface of Appendix showed Thickened Appendiceal Wall with Mucinous Area and Occluded Lumen. **B.** Sections from Appendix showing Ucedared Appendiceal Mucosa and a Neoplasm Arranged in Glands and Clusters of Tumour Cells Predominantly in Submucosa and Muscularis Propria. (H&E, 40X). **C.** Glands and Clusters of Tumour Cells with Extracellular Pools of Mucin Infiltrating through the Muscularis Propria into the Serosa. (H&E, 100X). **D.** The Tumour Cells are Round to Polyhedral with Intracytoplasmic Mucin and Pleomorphic Dark-Staining Nuclei. (H&E, 400X). **E.** Immunohistochemistry: the Tumour Cells showed Diffuse Strong Cytoplasmic Positivity for Cytokeratin 20. (40x). **F.** IHC (400X).

DISCUSSION

Appendiceal neoplasms are rare and most often found incidentally in an appendectomy specimen. Primary mucinous adenocarcinoma of the appendix is very rare accounting for 0.05% to 0.2% of all appendectomies and only 6% of all malignant tumour of the appendix. It constitutes less than 0.5% of all GI neoplasms. The incidence of adenocarcinoma has been stated to be from 0.004% to 0.08%.

The mean age at presentation for mucinous adenocarcinoma is about 50 years with a male preponderance of 4:1. Adenocarcinoma of appendix most often present as acute appendicitis, this may be due to distension of the appendix causing pain or from a superadded infection or as a palpable abdominal mass or with intestinal obstruction, but some are entirely asymptomatic. Mucinous neoplasms of appendix can also present with uncommon anatomical abnormalities such as intestinal malrotation or situs inversus. Since distant metastasis and viscera involvement are very rare, death occurs mostly due to loss of intestinal function and obstruction by peritoneal implants. Carcinoma appendix is usually well-differentiated mucinous adenocarcinoma, which tend to perforate and produce pseudomyxoma peritonei and do not metastasise until late in the disease process. The term for extensive spread of these tumours in the abdomen is Primary Mucinous Carcinomatosis (PMCA). According to WHO, the neoplasms of the appendix have been classified as epithelial and non-epithelial tumours (Table 1). Recently, Midraji et al. classified the mucinous tumours of the appendix into three subtypes. They are:

1. Low-Grade Appendiceal Mucinous Neoplasm (LAMN), which are adenomas confined to appendix or various alterations of the muscularis mucosa or wall.
2. LAMN with peritoneal spread having low malignant potential.
3. Invasive adenocarcinoma.

Histopathological evidence of invasion of the appendiceal wall by the atypical glands and identification of epithelial cell in any in intraperitoneal mucinous collection are the characteristic features of malignancy. Mucinous histology has a better prognosis than the colonic and goblet cell type. The optimal management for mucinous adenocarcinoma of appendix is right hecomectomy. Immunohistochemically, these tumour cells are positive for CDX2, MUC2, β-catenin, and CK20.

Molecular biology is similar to that of colorectal adenocarcinoma. Precursor lesions are villous polyp and serrated polyp. Similar to the large intestine, an adenoma-carcinoma sequence is assumed to occur in the appendix as well. KRAS mutations have been identified in 70% of cases and loss of heterozygosity (LOH) at 5q22, 6q, 17p13, and 18q21 are also identified. LOH at 5q is frequently linked to adenomatous polyposis coli (APC). LOH at one or two polymorphic microsatellite loci are seen in approximately half of the cases.

Five year overall survival rate for localised adenocarcinoma to be 95% compared with 5-year survival rate of 80% for mucinous or cystadenocarcinoma. When distant metastases were present, the 5-year survival rate was 0% and 51% respectively. This reflects the low aggressive potential of mucinous tumour that spread to the peritoneum.

It must be emphasised that up to 35% of the patients with appendiceal adenocarcinoma is more likely to have a second GI malignancy that underlines the significant risk for both synchronous and metachronous neoplasms.

CONCLUSION

Appendiceal mucinous adenocarcinomas are rare and usually diagnosed when patient presents with pain, mass in RIF, or intestinal obstruction. Histopathological examination of all appendectomy specimens is mandatory to rule out malignant pathology. The incidence of primary appendiceal adenocarcinoma in our institute is 0.005%, which correlates with that described in literature.
