ABSTRACT

CONTEXT

Perinatal asphyxia happens in 2 to 10 per 1000 newborns that are born at term, and more for those that are born prematurely and making one of the leading cause of death worldwide.

AIM

To study the pattern of involvement of brain in HIE influenced by nature of insult and to assess the severity of brain injury by MR imaging and correlate with clinical staging (Sarnat criteria).

METHODOLOGY

43 cases with history of perinatal asphyxia were included in this study by applying the inclusion criteria and exclusion criteria. Signal changes in T1 and T2 weighted images and diffusion weighted were assessed and recorded.

RESULTS AND INTERPRETATIONS

After MR imaging, most of the Sarnat Stage I and II patients were mild and stage III patients were severe. Of the all clinically diagnosed having HIE, 25.6% cases were normal. Patients with clinically mild hypotension >1/2 (54.2%) of them were found to be normal after imaging. Patients with clinically moderate hypotension, 20% were normal at MRI; and >1/2 (52%) of them showed only mild changes and 12% showed severe involvement. Term babies with mild encephalopathy shows more involvement of periventricular white matter than subcortical white matter. Clinically severe encephalopathy correlates with abnormal basal ganglia – thalamic lesions in term babies and germinal matrix haemorrhage in preterm babies. Clinically moderate encephalopathy correlates with signal changes in posterior limb of internal capsule and periventricular white matter. Prematurity increases the susceptibility of brain to changes caused by hypoxia. No significant association noted between sex and birth weight with abnormal MR imaging findings. The low Apgar score shows significant association with severity of brain involvement. Seizure and its onset also appears to be a deciding parameter in severity of brain injury.

KEYWORDS

HIE - Hypoxic Ischaemic Encephalopathy, MRI - Magnetic Resonance Imaging, DWI - Diffusion Weighted Imaging, T1WI - T1 Weighted Imaging, T2WI - T2 Weighted Imaging, ADC - Apparent Diffusion Coefficient.

INTRODUCTION

Perinatal asphyxia happens in 2 to 10 per 1000 newborns that are born at term and more for those that are born prematurely. A 2008 bulletin from the World Health Organization estimates that a total of 900,001 total infants die each year from birth asphyxia, making it a leading cause of death for newborns (As per 2013 statistics).

Magnetic Resonance Imaging (MRI), an increasingly available and non-invasive examination (may be performed during the child’s physiological sleep), which unlike the computed tomography does not involve the child’s exposure to X-ray. MRI allows to reveal a number of lesions associated with HIE that are invisible on the ultrasound scans.

Another MRI advantage is the possibility to predict the clinical consequences of hypoxic-ischaemic lesions. Magnetic Resonance Imaging (MRI) with its ability to detect certain abnormalities of tissue water in response to injury has been one of the widely used tool of diagnosis in both paediatric clinical and experimental application.

AIMS AND OBJECTIVES

• To study the pattern of involvement of brain in HIE influenced by nature of insult.
• To assess the severity of brain injury by MR imaging and correlate with clinical staging (Sarnat criteria).

METHODS

Study Design: Descriptive study.

Study Setting: Radiology Department Govt. Medical College, Kozhikode.

Study Period: Data collection was done in January 2013-February 2014.

Sample Size: 43 subjects.
Inclusion Criteria
Newborns with perinatal asphyxia and signs suggestive of HIE, who are undergoing imaging in our institution.

Exclusion Criteria
Newborns with congenital malformations and congenital infections.

Study Method
- MRI with a 1.5 T MR system (GE SIGNA HDXT).
- Axial (FSE) pulse sequence T1WI - (TR/TE, 205-730/4-16 ms) and T2WI - (TR/TE, 1553-5897/80-200 ms) fast spin echo, fluid attenuated inversion recovery sequences (TR/TE/TI, 8000/110-120/1860-2000 ms), T2WI in sagittal plane and Gradient Echo Planar Image (EPI) DWI pulse, b-value 0, 600 second/mm2.
- ADC values are calculated within the lesion, diameter of ROI - 31.2 mm.

Statistical Analysis
- SPSS statistical software.
- P value </= 0.05 statistically significant difference.

STUDY METHODOLOGY
After getting informed consent from the parent, the socio-demographic details and the antenatal details of the mother, the clinical symptoms of asphyxiated newborn, history of seizure, feeding difficulty, reflex, tone, birth weight, Apgar, NND of imaging and maturity at birth are collected. They were included if they fulfilled the following criteria (Suggestive of perinatal asphyxia).

1. Signs of foetal distress before delivery (Abnormal cardiotocographic recording such as decreased variability, late deceleration, baseline bradycardia or Meconium stained liquor).
2. Apgar score of <7 after 5 minutes.
3. Clinical signs of hypoxic-ischaemic encephalopathy.

Clinical Criteria for Diagnosis of HIE
- Evidence of foetal distress (Abnormal CTG, Meconium stained liquor).
- Low Apgar at birth.
- Necessity of resuscitation.
- Neurological signs.

Sarnat Clinical Grading of HIE
Mild-irritability
- Alternating levels of consciousness.
- Poor feeding.
- Exaggerated moro/tendon reflexes.
- Muscle tone - normal to increase.
- Seizure - absent.

Moderate
- Lethargic.
- Exaggerated tendon reflexes.
- Muscle tone - decreased.
- Seizure within 24 hrs.

Severe
- Coma.
- Flaccid tone.
- Seizures.
- Brainstem and autonomic dysfunction.

MRI Criteria
After doing MRI, ischaemic injury has to be appreciated by detecting abnormal signal intensities in the following areas - Subcortical white matter and (+/-) cortex, Posterior Limb of Internal Capsule (PLIC), Perirolandic White Matter (PRWM), Periventricular White Matter (PVWM), basal ganglia, thalami and brainstem. Data was entered as T1 hypo/hyper, T2 hypo/hyper, DWI+/_. Cases were classified as mild, moderate or severe. The pattern of injury was classified according to the abnormalities seen, as previously described by Christine P. Chao et al.1

In term babies SCW+/C-taken as mild, PRWM and PLIC - Moderate and brainstem, basal ganglia and thalami-severe. In preterm babies PVWM-mild germinal matrix bleed/basal ganglia and thalami lesions-severe.

Ethics
The study was approved by the Institutional Research Committee and Ethics Committee of Government Medical College, Kozhikode, Kerala, India.

Statistics
The Null Hypothesis (H0) assumes that there is no association between the predictor and outcome variables in the study population. When we conclude that there is statistical significance, the P value tells us what the probability is that our conclusion is wrong when in fact H0 is correct. The lower the P value, the less likely that our rejection of H0 is erroneous. By convention, most analysts will not claim that they have found statistical significance if there is more than a 5% chance of being wrong (P=0.05).

Table 1: Frequency Distributions by Gestational Age

In this study group which comprised of total number of 43 newborn babies, 37 (86%) cases were term and 6 (14%) cases were preterm.

Fig. 1: Frequency Distribution of MRI Findings According to Gestational Age

Severity of brain injury in HIE is found to be increased in preterm newborns, (50% were severe), whereas majority of term babies showed only mild involvement (48%). On
performing $X^2$ test to check an association, the P value was found to be 0.05, which is statistically significant. So that according to this study, there is significant association between foetal maturity and brain injury in birth asphyxia and the chance of finding a severe MR abnormality is definitely high.

It is observed that most commonly affected areas are periventricular white matter followed by cortex +/- subcortical white matter.

Babies with low birth weight appear to be more commonly affected and show severe brain involvement on comparison to normal birth weight babies. P value for this association was 0.115 (>0.05). According to this study, there is no statistically significant association between birth weight and abnormal MR finding in patients with HIE.

Babies with low Apgar at 5 minutes appear to be more commonly affected and show severe MRI abnormalities. On performing $X^2$ test to detect association between Apgar and MRI findings revealed P value of 0.01 (<0.05), which appears to be significant. So that according to this study, there is significant association between low Apgar score and brain injury in birth asphyxia and the chance of finding a severe MR abnormality is definitely high.

Severe involvement of HIE is common in males compared to females. However, $X^2$ test to determine association between sex and MRI finding revealed P value of 0.112 (>0.05). Hence, according to this study, there is no statistically significant association between sex of the patient and chance of finding an abnormal MRI pattern in patients with HIE.
Those having seizure within 24 hours, 80% were having abnormal MR findings. Out of this, majority were mild (62.2%); 18.7% were severe. Those having seizure after 24 hours, all cases showed abnormal MRI finding and about 50% of them were severe. Out of all cases having seizure irrespective of time of onset, 84.8% showed involvement in MRI and delayed onset of seizure is correlating with severity of brain involvement. P value for this association was 0.05, which appears to be significant.

When the X² test was done to find out the association between clinical grading and MR diagnosis, the P value was found to be 0.004 (<0.005), which appears to be significant.

To interpret that there is >50% chance of getting normal MRI study even in patients clinically graded as mildly affected. And only <50% shows mild brain injury in this group. In patients clinically having moderate HIE, there is a chance of finding a normal MRI study in 20% cases and mild involvement is 50%. In those who are clinically severe, >57% had severe involvement in MR and none were normal.

**Representative Cases**

**CASE 1**
Axial T2WI MR image showing hyperintense signal involving cortex and subcortical white matter of bilateral posterior water shed territories in a term baby.
CASE 2
ADC image showing hypointense signal involving bilateral ventromedial thalami and left lentiform nucleus in a term baby with history of severe hypoxia.

CASE 3
Axial T2WI image (Fig. 3) in term neonate within 8 hrs. of delivery showing no abnormal signal. Diffusion weighted image (Fig. 4) showing hyperintensity in anterior pons in the same patient and ADC image (Fig. 5) showing hypointensity in the same region.
CASE 4: Axial T1W images showing abnormal hyperintense signals in left perirolandic white matter. Axial T2W images of same patient showing abnormal hyperintense signal in the left perirolandic white matter.

CASE 5: Axial T2W images in a preterm neonate showing bilateral multicystic encephalomalacia (R) > (L).

CASE 6: Axial GRE images in a preterm neonate with germinal matrix bleed showing blooming artefacts.

DISCUSSION
After MR imaging, most of the Sarnat Stage I and II patients found in mild category and stage III patients found in severe category. Of the babies clinically considered having mild hypotension >½ (54.2%) of them were found to be normal after imaging. Of the babies clinically having moderate hypotension, 20% were normal at MRI; and 52% of them showed only mild changes and 12% showed severe involvement. Of those having profound hypotension more than half of them revealed primary involvement in thalamus, basal ganglia and brain stem. These observations were found in study conducted by Kaufman SA et al. Mild encephalopathy correlates with normal MRI result, severe encephalopathy correlates with abnormal basal ganglia and moderate encephalopathy manifested basal ganglia abnormality with a likelihood ratio of 0.785.

Severity of Involvement
In term babies with mild HIE, 72.2% showed signal changes in SCW. This observation was similar to study by Van Den Bergh R et al and Takashima S, Tanaka K. They observed that term infants who suffer similar degrees of hypotension sustain injury in the watershed portions of the cerebral cortex and in the underlying subcortical and periventricular white matter. Classically, this change in injury pattern has been attributed to a changing location of the intervascular boundary zones.
In this study, percentage of abnormal MRI findings were more among low birth weight babies compared to normal birth weight babies and in male babies compared to female. However, it was not statistically significant.

CONCLUSION

- MR pattern of brain damage in patients with prolonged partial asphyxia is seen to evolve in a predictable manner corresponding to the known maturation of brain and its vascular supply.
- In this study, more than half of clinically mild cases and 20% of clinically moderate cases were found to be normal after MR imaging. Hence, this study signifies the value of MRI in excluding unaffected patients from those clinically considered as mildly or moderately asphyxiated and the need of MRI to be performed in all patients with clinical diagnosis of HIE by Sarnat’s criteria.
- In this study, term babies with mild encephalopathy shows more involvement of periventricular white matter than subcortical white matter.
- Periventricular white matter involvement observed in term babies with clinically mild HIE may be due to immature zones of myelination or due to ischaemia itself. In such cases, follow-up imaging is advised later for confirmation.
- Clinically severe encephalopathy correlates with abnormal basal ganglia-thalamic lesions in term babies and germinal matrix haemorrhage in preterm babies.
- Clinically moderate encephalopathy correlates with signal changes in posterior limb of internal capsule and periorolandic white matter.
- This study shows statistically significant association between prematurity and severe brain involvement in HIE.
- This study highlights the importance of MRI in neonates with low Apgar at 5 mins., as these cases show severe involvement in MRI and there is statistically significant association between low Apgar score and brain injury in birth asphyxia.
- This study signifies the association between time of onset of seizure in asphyxiated neonates and severity of brain involvement.
- In this study, percentage of abnormal MRI findings were more among low birth weight babies compared to normal birth weight babies and in male babies compared to female. However, it was not statistically significant.
