ABSTRACT

BACKGROUND

An intertrochanteric fracture occurs between the greater trochanter and the lesser trochanter, which is common in old age. If treated non-operatively, malunion with coxa vara deformity resulting in shortening of limb are commonly seen. Intertrochanteric femur fractures may be fixed with either a sliding hip screw or an intramedullary nail. Problem with sliding hip screw is collapse of the femoral neck, leading to loss of hip offset and shortening of the leg. Therefore, a new intramedullary device - proximal femoral nail (PFN) was designed which gave an advantage of minimally invasive surgery.

Objectives-To determine the functional outcome of intertrochanteric fracture treated with proximal femoral nail (PFN) by using Harris Hip Score (HHS).

MATERIALS AND METHODS

A prospective study was done among 47 patients of both gender who had undergone proximal nail fixation for intertrochanteric fractures. Patients were followed up for a period of 12 months. Functional outcome was assessed by Harris Hip Score (HHS).

RESULTS

Most of the study subjects were in 81-90 years age group (34%). Out of 47 patients, 63.8% were female and 36.2% were male. In majority, right side (55.3%) was affected. The mean post-operative day of mobilisation was 2.45±0.169 days. The mean HHS score among the study subjects was assessed to be 83.83 ± 8.36. Almost 78% patients got good to excellent functional outcome according to Harris Hip Score.

CONCLUSION

In this study, use of proximal femoral nail in the treatment of intertrochanteric fractures produced better functional outcomes in majority of the patients.

KEYWORDS

Intertrochanteric Fracture, Proximal Femoral Nail, HHS.

BACKGROUND

An intertrochanteric fracture occurs between the greater trochanter, where the gluteus maximus, gluteus medius and minimus muscles (Hip extensors and abductors) attach and the lesser trochanter, where the ilipsoas muscle (Hip flexor) attaches. The trochanteric fractures can be managed by conservative methods and there is usually union of the fracture. In trochanteric fractures, treated non-operatively, malunion with coxa vara deformity resulting in shortening of limb are commonly seen.1 It is also associated with complications of prolonged immobilisation like bedsores, deep vein thrombosis and respiratory infections.

To address this, various operative procedures with different implants have been described for the treatment of intertrochanteric fractures. The primary goal of the treatment is early mobilisation, which can be achieved by internal fixation. Intertrochanteric femur fractures may be fixed with either a sliding hip screw or an intramedullary nail. A problem with sliding hip screw is collapse of the femoral neck, leading to loss of hip offset and shortening of the leg. Therefore, a new intramedullary device- proximal femoral nail was designed by AO in 1996 which gave an advantage of minimally invasive surgery.2 Proximal femoral nail fixation has advantages over sliding hip screw and plate like 1. Biomechanically sound fixation. 2. Minimally invasive surgery. 3. Load bearing device. 4. Less stress riser effect at tip of nail. 5. Facilitates early mobilisation of patients especially elderly. 6. Controlled concentric collapse at fracture site leading to shortening can be minimised or prevented.4,5 7. Less incidence of varus collapse.5,6,7 8. Shorter operative time and less soft tissue dissection. Objective of the study was to determine the functional outcome of intertrochanteric fracture treated with proximal femoral nail (PFN) by using Harris Hip Score (HHS).8
MATERIALS AND METHODS
A prospective study was done among 47 patients of both gender who had undergone proximal nail fixation for intertrochanteric fracture in Orthopaedic Department of Amala Institute of Medical Science, Thrissur. Patients were followed up for a period of 12 months (February 2014 to February 2015). A brief history and clinical examination were carried out for every patient. Functional outcome was assessed by Harris Hip Score (HHS). Written informed consent was taken from all patients. Data collected was entered in Microsoft excel and was analysed using Epi info software. Ethical approval was obtained. All patients were followed up at 6 weeks till fracture union was noted and then reviewed every 3 months till 1 year. During every visit, patients were assessed regarding hip and knee function, walking ability, fracture union, shortening, and deformities. Harris Hip Score was used for evaluation of functional outcome.

The Harris Hip Score interpretation (HHS).

The hip score gives a maximum of 100 points. Pain receives 44 points, function 47 points, and deformity 9 points. The higher HHS, the less dysfunction.

Total Score
<70 - poor, 70–79 – fair, 80–89 – good, 90–100 – excellent.

RESULTS
A total of 47 patients having intertrochanteric fractures treated with standard proximal femoral nail were assessed for functional outcome. The mean post-operative follow up period was 12 months.

Distribution of the Study Subjects according to Gender
Out of 47 patients 30 (63.8%) were female and 17 (36.2%) were male.

DISCUSSION
In this study, female population (63.8%) was more affected compared to males owing to the fact that they are more osteoporotic. A study conducted by Melton J. L., Ilstrup DM, Riggs BL et al (1982) titled ‘fifty years trend in Hip fracture incidence’ and reported a female to male ratio of 1.8:1.7 According to a study by Scott in 1951 & Robey in 1956, the male to female ratio was 1.85 and 1.15 respectively. Cleveland et al5 in their study had 87.7% of female patients. H. B. Boyd and L. L. Griffin36 in their study of 300 cases, 226 (75.8%) of the patients were female and 74 (24.2%) were male. Most of the patients in this study were elderly people. The mean age of patients in this study was 75.21 years. This indicates the fact that patients from these age groups are involved in low energy trauma like domestic fall (Fall at home).11 According to Gallagher et al (1980), there is an eight fold increase in trochanteric fractures in men over 80 years and women over 50 years of age. Nuber S Schonweiss et al (2005) observed the mean age of 81.5 years in their study.
Huang et al (2010) observed in their study, the mean age of 75 years. The proximal femoral nail fixation has small incision, less blood loss, minimum soft tissue dissection, less duration of surgery and low morbidity. This technique facilitated early mobilisation of the patient. Most of the patients in this study started mobilising on the second postoperative day. This was followed by bed-to-chair transfer, non-weight bearing mobilisation with the help of walkers. Almost 78% patients got good to excellent functional outcome according to Harris Hip Score. Only 4% of the patients had poor functional outcome. The Harris Hip Score shows that proximal femoral nail fixation has advantages in functional outcome.

CONCLUSION
In this study, use of proximal femoral nail in the treatment of intertrochanteric fractures produced better functional outcome in majority of study subjects. So this treatment can be recommended for good results in the management of intertrochanteric fractures.

Acknowledgment
I express my heartfelt gratitude to my all colleagues in the department for their painstaking efforts in completion of this study in a better way.
