ABSTRACT

INTRODUCTION

One of the important reasons behind most of the maternal and neonatal morbidity as well as mortality is preeclampsia and complications associated with it. (1,2) Abnormal placentation being etiology for the same. Normally during placentation development, trophoblastic invasion occurs in two phases. First phase at 8 to 12 weeks where there is trophoblastic invasion up to intradecidual portion of the spiral artery. This lead to placental hypoperfusion and reduction in the blood supply.(3,4) Normally because of invasion of the endovascular trophoblasts into walls of spiral arterioles of uteroplacental bed, there is replacement of endothelial lining and muscular arterial wall by fibrinoid formation. This physiological change transforms uteroplacental vasculature from high resistance into low resistance low pressure system. In preeclampsia as there is failure of endovascular trophoblastic migration together with endothelial dysfunction and vasospasm, there is high resistance flow in the uteroplacental bed.

Second phase commences from 14 weeks with deeper myometrial trophoblastic invasion. This placental remodelling is completed by 16-18 weeks underlying basic pathophysiology of preeclampsia is failure of endovascular trophoblastic migration.(3,4) Normally because of invasion of the endovascular trophoblasts into walls of spiral arterioles of uteroplacental bed, there is replacement of endothelial lining and muscular arterial wall by fibrinoid formation. This physiological change transforms uteroplacental vasculature from high resistance into low resistance low pressure system. In preeclampsia as there is failure of endovascular trophoblastic migration together with endothelial dysfunction and vasospasm, there is high resistance flow in the uterofetalplacental unit. This lead to placental hypoperfusion and reduction in the blood supply. (5,6,7,8)

Doppler ultrasound is a non-invasive method for examining uteroplacental circulation. There are ample

METHODS

This is a prospective study. Total 250 antenatal patients were included. These patients were offered ultrasound examination at 11 to 14 weeks of gestational period. Left and right uterine artery was examined by colour and pulsed Doppler. Mean Pulsatility Index and presence of diastolic notch if any was noted. These patients were followed for occurrence of preeclampsia or any other complication. Pregnancy outcome in both the group was studied. Risk ratio was calculated.

RESULTS

In 96% of the patients, satisfactory uterine artery Doppler waveform was noted. All the patients were followed till date of delivery to study pregnancy outcome and occurrence of preeclampsia or related complications if any; 95th centile of mean pulsatility index obtained was 2.35 which is constant with gestational age. Patients with abnormal uterine artery Doppler at 11–14 weeks had more incidences of preeclampsia (RR 3.5), intrauterine growth restriction (RR 3) and related complications (RR 5.8) than patients with normal Doppler.

CONCLUSION

Our study noted that the patients with preeclampsia and associated complications had uterine artery Doppler changes in ultrasound study done at 11 to 14 weeks. So we conclude that the Doppler study done at earlier gestational age is useful in predicting preeclampsia in later gestational period.

KEYWORDS

Uterine Artery Doppler Preeclampsia Predictor.

evidences, which suggests role of uterine artery Doppler in second trimester as a predictor of developing preeclampsia and associated complications.\textsuperscript{(9,10,11)} But if investigations done in early gestational period can predict further complications well in advance, then preventive measures and monitoring can be started more effectively since early gestational period.

By which we can reduce burden of raised morbidity associated with the same. There are studies carried out to predict preeclampsia and associated complications in late first trimester or early second trimester.

Uterine artery Doppler study at 11–14 weeks can promise this early prediction.\textsuperscript{(12,13,14,15)} With this background we have studied significance of the Doppler study in early pregnancy in predicting the risk of preeclampsia.

**MATERIALS AND METHOD**

This study is done at RCSM Government Medical College and Chhatrapati Pramila Raje Hospital, Kolhapur, over a period of 12 months. Women attending routine antenatal clinic were counselled and offered Doppler ultrasound at 11 to 14 weeks of gestation. Written informed consent obtained. Rules and regulations of PCPNDT act were followed. Women placed in supine position and transabdominal ultrasound was performed, so as to get sagittal view of uterus and cervical canal. Internal os of the cervix was first noted, then uterine artery was located by tilting the probe sideways and with the help of Doppler colour flow mapping.\textsuperscript{(15)} Three consecutive wave forms were obtained and pulsatility index was noted. Mean pulsatility index, resistance index was obtained from right and left uterine arteries. Presence of any diastolic notch was noted.

Gestational age calculated by last menstrual date and confirmed by crown rump length. Characteristics of patients like maternal age, significant past history, family history and any risk factor for developing hypertension were noted. These patients were followed till delivery to study their pregnancy outcome.

Outcomes were measured in terms of presence or absence of preeclampsia, intrauterine growth restriction or any complications associated with it.

Preeclampsia is defined as raised blood pressure above 140/90 mmHg post 20 weeks in previously normotensive patient with at least two readings 6 hrs. Apart with proteinuria more than or equal to 300 mg per 24 hrs or more than ++ in midstream urine sample.\textsuperscript{(8)} This definition is as per international society of study of hypertension in pregnancy. Foetal growth restriction is defined as less than tenth centile of the normal birth weight in the local population. Gestational age at delivery calculated using last menstrual date and first trimester gestational age by CRL. Complications associated with preeclampsia studied in this study are placental abruption, eclampsia, impending eclampsia, intrauterine death.

**Inclusion Criteria**

All pregnant women registered for antenatal care irrespective of parity who are willing to participate in the study.

**Exclusion Criteria**

Patients with congenital anomalies or chromosomal abnormalities.

Patients on low dose aspirin or heparin as prophylactic measures. Patients with known hypertension with antihypertensive drugs prior to pregnancy.

**STATISTICS**

Pearson’s Chi Square test or Fisher’s exact test is used to study categoric variables and unpaired ‘t’ test is used for studying continuous variables. Thus normal and abnormal Doppler results with incidences of preeclampsia and its complications were studied. Abnormal results in terms of more than 95\textsuperscript{th} percentile of pulsatility in preeclampsia, IUGR complications were calculated.

**RESULT**

Total 250 antenatal patients were included in this study, out of which 6 patients had miscarriage, 4 patients had termination of pregnancy because of congenital anomalies, 8 patients got lost for followup. Pregnancy outcome in remaining 232 patients were studied.

Of these 232 patients in 96% (223) of patients satisfactory Doppler with three uniform wave form was obtained, mean pulsatility index was calculated. Of all the studied patients, patients who had normal (128) Doppler findings; 8% of the patients developed preeclampsia (10), 6% had IUGR (8) (without preeclampsia), 2.6% developed severe preeclampsia complications like abruption, eclampsia, impending eclampsia, intrauterine demise, renal failure, DIC (5). Amongst patients with abnormal Doppler findings (95), 28% had preeclampsia (47), 20% had IUGR (17), 15% developed severe preeclampsia complications (15) which is statistically significant (P value <0.05). Risk ratio was calculated according to which patients with abnormal Doppler reports were three and a half times at risk of preeclampsia, two times at risk of associated severe complications and three times at risk of IUGR.

**Table 1: Demographic Characteristics and High Risk Factors**
The 'great eclampsia: number 33 hypertensive disorder - irritated vascular remodeling and syndromes' are associated with disorders of abnormal or ed with abnormal uterine Doppler findings and complications. This theory lead to concept that uterine Doppler changes together with maternal high risk factors will lead to group of patients, which will present with severe forms of hypertensive disorders of pregnancy. Therefore maternal predisposing factors should be combined with abnormal or normal uterine Doppler changes. Therefore, uterine Doppler changes would be useful in predicting only those cases with severe placental ischemia from early stages of pregnancy.

In summary our study suggests there is role of uterine artery Doppler in predicting high risk for preeclampsia and related complications.

**CONCLUSION**

It is necessary to identify group of high risk population in early stage of pregnancy. Our study concludes that Doppler study done at earlier gestational period (11-14 weeks of gestation) is useful in predicting adverse pregnancy outcomes. Earlier the risk is known, effective monitoring and prophylactic measures can be started from early gestational age.
