CASE REPORT

COMPOUND DORSAL GANGLION WITH RICE BODIES

HOW TO CITE THIS ARTICLE:

ABSTRACT: BACKGROUND: Tuberculosis has decreased persistently since the introduction of antituberculous chemotherapy. However there are reports in recent literature indicating that rate of tuberculosis is increasing. Musculo skeletal tuberculosis occurs in approximately 1-3% of tuberculosis patients. Tuberculosis of soft tissue such as tenosynovial sheath or bursa is rare. We are presenting a rare case of compound dorsal ganglion which is accompanied by multiple rice body formation without co existing active bone and joint tuberculosis. OBJECTIVE: to describe history clinical and radiologic presentation of compound dorsal ganglion and management. METHODS: Detailed history, physical examination and investigations. CONCLUSION: We report a unique case of compound dorsal ganglion with rice bodies formation in absence of any other concomitant focus of tuberculous infection, managed with excision biopsy and anti - tuberculous regimen. KEYWORDS: mycobacterium infections, tuberculosis, ganglion, granuloma, rice bodies.

INTRODUCTION: Rice body formation is commonly observed in the joint and tendon sheaths among patients with rheumatoid arthritis, however only a few cases with rice bodies of tubercular origin have been mentioned in the literature.

Tuberculosis of the bone and joint occurs in approximately 1% to 3% of patients with tuberculosis. The most common type is spondylolitis which accounts for 50% of all cases followed by Peripheral arthritis and osteomyelitis. Involvement of extensor and flexor tendons may result. Totally, tenosynovitis and bursitis account for approximately 1%.

Both primary tuberculous teno synovitis and bursitis are rare conditions.

CASE REPORT: A 70 yrs male patient presented with painless swelling over the dorsum of his right wrist joint since 1 year. Patient noticed the swelling 1 year back, which initially was of lemon size over the dorsum of his right wrist, gradually increased and attained the present size. On physical examination there was a single 8x4cm dumbbell shaped mass, which appeared to be two swellings but were contiguous on palpation. No local rise of temperature and no tenderness over the swelling. surface was smooth and the borders were well defined. Skin was pinchable and the mass was freely mobile in transverse axis. Swelling was soft and cystic with fluctuation positive, transillumination negative. No restriction of range of movements. No other joints involved. Regional lymph nodes were not palpable.

No history s/o pulmonary koch’s such as chronic cough, constitutional symptoms.
No history of trauma. No history of contact with tuberculosis.
Investigations revealed the wbc count was 8,500/cmm. With lymphocytes being 29%. Erythrocyte sedimentation rate was 10mm, c reactive protein concentration level normal.
Radiography was normal except for soft tissue swelling. Chest radiography did not show any evidence of primary lesion.
USG of the swelling was suggestive of what appeared to be a ganglion cyst.
FNAC of the mass revealed few scattered oval cells with abundant pink cytoplasm against bluish mucoid background, suggestive of ganglion.

Patient underwent wide excision biopsy of the expected diagnosis of the ganglion cyst. There were a few soft tissue adhesions and the mass was attached to the extensor tendons under the extensor retinaculum but it did not appear to have any extension deep into the wrist joint. The retinaculum was incised open. The mass was excised along with the thickened tenosynovium. Gross specimen findings revealed lobulated mass with thick white membrane. On cut sections, there were rice bodies filled inside the mass. Rice bodies macroscopically resembled shiny white rice grains, size consistency and shape varied and more than half of them being in between 2 to 8 mm length.

Histopathological examination revealed well defined granulomatous areas showing collections of epitheloid cells, Langerhans Giant Cells, and lymphoid cells with adjoining eosinophilic acellular areas.
DISCUSSION: Primary tuberculous tenosynovitis and bursitis are rare conditions. Rice bodies occurring in joints due to TB was first described in 1895. These are a common finding in rheumatoid arthritis, SLE, seronegative arthritis, tuberculosis, atypical mycobacterial infections and non-specific arthritis. Etiopathogenesis of tuberculous tenosynovitis may be either due to direct inoculation or due to hematogenous spread. However the later doesn’t seem to be a source in this case as there were not even healed TB lesions.
The cause of rice body formation remains obscure. Some authors proposed a synovial origin with microinfarction leading to synovial sloughing and subsequent encasement by fibrin derived from synovial fluid. Others thought that earliest rice bodies are formed denovo in synovial fluid independently of synovial elements and that their presence is due to progressive enlargement of fibronectin/fibrin aggregates.

CONCLUSION: We report a unique case of tuberculous tenosynovitis with rice body formation in absence of any other concomitant focus of tuberculous infection, managed with wide excision and category I anti-tuberculous regimen according to DOTS (Directly observed treatment short course).
