ABSTRACT

BACKGROUND
Laparoscopic cholecystectomy is the gold standard treatment for symptomatic gall stones.1 Port site infection (PSI) is a common complication of laparoscopic cholecystectomy which often proves problematic and nagging for the patient and the operating surgeon; the former being affected by increased morbidity in terms of pain, suboptimal level of wellbeing, increased hospital stay, emotional turmoil, and increased economic loss.

MATERIALS AND METHODS
The present study was a prospective observational study conducted on 620 patients who underwent laparoscopic cholecystectomy in Government Hospital, Sarwal, between February 2014 to January 2018. This involves the study of infection of port site following lap cholecystectomy over a period of four years and aims to minimise the incidence of PSI which is showing a latest trend from polymicrobial to atypi form. Out of 620 patients, 600 patients were operated with 3 ports and 20 patients with 4 ports.

RESULTS
PSI was determined to be 4.67% and was most commonly due to Staphylococcus aureus though atypical microorganisms were the causative agents in some cases. The commonest site of post-surgical infection was the epigastric port.

CONCLUSION
PSI is a commonly observed complication following laparoscopic cholecystectomy. With the passage of time, common pyogenic organisms are being replaced by atypical organisms.

KEY WORDS
Laparoscopic Cholecystectomy, Port Site, Complication, Morbidity, Atypical Bacteria.

During the surgery, the gall bladder was removed through the epigastric port. The requirement of fourth port was more in males. It was needed in 20 patients in our study. The total incidence of PSI was 4.67% and was most commonly seen at the epigastric port. (Table-2)

The dressing was changed after 24 hrs and stitches were removed on 8th post-operative day. In cases with any sign of infection, the culture was taken from the wound and sent for microbiological examination and the treatment was started as per the report of the culture.

Incidence of infection was more with prolonged procedure, increasing age of the patient, male sex and any coexisting disease.

The treatment of the wound depends on the type of microorganisms present in the culture. The laparoscopic instrument used during the study were sterilised by 2% glutaraldehyde solution with a contact time of 20 minutes before surgery and were washed with warm saline before use.

RESULTS
In the present study, out of 620 patients only 29 cases had port site infection so the incidence of PSI in this study was 4.67%. Amongst 620 patients studied 496 were females and 124 were males. The PSI was seen in 19 out of total 124 cases in males and in 10 out of total 496 cases in females. Therefore, the PSI was 15.32% in males and 2.01% in females. Surgery was done using three ports in 600 patients and only in 20 patients fourth port was used. PSI was seen in 24 cases out of total 29 at the epigastric port and only in 5 cases it was seen at the umbilical port. The infection was mainly superficial.

Organisms detected after microbiological examination of culture were as follows
1. Staphylococcus aureus,
2. Pseudomonas,
3. Klebsiella,
4. Actinobacter,
5. Escherichia coli,
6. Enterobacter faecalis,
7. Bacteroides fragilis,
8. Mycobacterium fortuitum,
9. Mycobacterium chelonae,
10. Mycobacterium abscessus.

DISCUSSION
All surgeries have an inherent risk of infection, but the risk is relatively less in case of laparoscopic or minimal access surgery. PSI, a preventable entity, has become a sore eye of the minimal access surgeon. Though infrequent, its occurrence can damage the reputation of the surgeon and can frustrate the patient. The emerging and rapidly changing bacterial flora is posing a real challenge to the treating surgeon. This study is likely to help the training surgeon to be aware of this complication while treating PSI so that proper treatment can be instituted at the earliest. Also, proper preoperative steps should be taken to prevent this complication to settle in. Many authors have studied the PSI after laparoscopy as shown in table-3.

Most of the authors like Mir et al, Shindholimath et al, S. S. Kumar et al., Den Hoed et al and Muhammad Naem Taj were of the opinion that the incidence of PSI is more than 5% but in our study it was less than 5% (4.67%). However some authors like Coliza et al have reported the incidence of PSI to be less than 2%. The present study is in accordance with study of Mumtaz KH Al-Naser 2017 where the incidence of PSI was 4.5 %. High level of disinfection can decrease the incidence of PSI that is the laparoscopic instrument should be dismantled and cleaned completely. However atypical microorganism show resistance to routinely used disinfectants. Incidence of PSI in present study was more at epigastric port which is in accordance with authors like Mumtaz KH Al-Naser. This was not in accordance with Dr SS Kumar and Muhammad Naem Taj where incidence was more at the umbilical cord. The port from where the gall bladder was extracted was most susceptible to infection, which was the epigastric port, in the present study. Similar observations were observed by Dr Narayan Das et al. As discussed by Richards C et al, the ten commandments to prevent PSI are

1. Use of disposable trocars and instruments and adequate availability of properly sterilized reusable trocars to cover all the surgical procedures in a day.
2. Use of autoclavable laparoscopic hand instruments.
3. Use of instruments with good ergonomics, limited joints and facility for proper cleaning of the debris collected in its crevices.
4. A proper cleaning of the instruments is best achieved by ultrasonic technology, use of autoclaved water for cleaning the instruments after dismantling.
5. Proper guidelines should be followed regarding the concentration, contact time and cycles of use for instruments sterilization with liquid sterilizing agents.
6. Use of plasma sterilizer or ethylene oxide in between the consecutive surgery for instrument sterilization.
7. Avoiding inter-departmental sharing of instruments such as using instruments for gynaecological or urological procedures.
8. Avoiding spillage of bile or gut contents in the operative area or the port site.
9. Use of non-porous specimen retrieval bags for retrieving the specimens.
10. Thorough irrigation and cleaning of the port site before closure.

CONCLUSION
Prevention is better than cure. PSI is a common but preventable complication after laparoscopic cholecystectomy as everything comes with a price tag. Its incidence can be decreased by proper sterilization of instruments. The infection is mostly superficial and seen at the site, from where the gall bladder is extracted. The infection is more common in males. The polymicrobial infection and infection caused by atypical mycobacterium have prolonged morbidity. Therefore, culture and determination of sensitivity to antimicrobials are important as such infections respond to macrolides, quinolones and aminoglycosides and not to standard antimicrobials. More research is needed to diagnose and treat this problem with proper notification of cause, incidence and antimicrobial sensitivity of port site infections following laparoscopic cholecystectomy.
