ABSTRACT

BACKGROUND

Intraocular Lens (IOL) power calculation is the most important step to achieve best refractive outcome in cataract surgery. Various studies had revealed that about 54% of the error in predicted refraction occurred due to inaccuracy in axial length measurement alone. Therefore, axial length measurement is the most important step to minimise these errors.

The aim of this study was to compare IOL power calculation using a manual method (Applanation ultrasound A-Scan and Keratometry) with the automated method (Optical Biometry).

MATERIALS AND METHODS

It was a prospective, comparative study. In this study, 200 eyes of 196 patients were analysed in the Department of Ophthalmology. Each eye underwent measurement by both methods, with manual method (Applanation Ultrasound A-Scan and manual Keratometry) and with automated optical biometry. Axial length and Keratometric readings were obtained and IOL power calculation was done by both the methods. Patient underwent clear corneal phacoemulsification cataract surgery within the IOL implantation in all the cases, then postoperative autorefration was noted in all cases in follow-ups.

RESULTS

The Mean Axial Length calculated by optical A scan was 23.02±1.00 mm and by ultrasound A scan was 22.93±1.03 mm. The mean difference in axial length between optical system and Ultrasound A scan was 0.087±0.039 mm, which is statistically not significant (p value 0.19). However, differences in axial length measurement were more when compared, for short eyes, by two devices. After analysis of Bland-Altman plot. All differences were within two standard deviations (95% confidence level) from mean differences (0.0869±0.038 mm, i.e. between 0.0096 mm and 0.1641 mm). The regression line between the two methods, Pearson’s correlation coefficient ‘r’ is 0.999, which evaluates excellent agreement of axial length measurement between two methods. The differences in mean IOL power between automated method and manual method was 0.43±0.38 D, which was statistically and clinically insignificant (p value 0.09).

CONCLUSION

To measure axial length and IOL power, optical biometry is very precise and interchangeable with ultrasound method. Optical biometry in short eyes gives better result in axial length measurement as compared to ultrasound A-scan.

KEY WORDS

A-Scan, Keratometry, Optical Biometry, IOL Calculation.

BACKGROUND

Cataract surgery has been changed from a purely surgical procedure to one of the refractive or "vision correcting" procedure.
optical biometry is becoming popular nowadays as it is easy to use, fast, operator independent and contact free method. The Lenstar LS 900 (Haag-Streit, USA) is optical Low Coherence Reflectometry (LCOR) based and uses a 820 nm super luminescent diode.[4] In developed nations, accurate and fast methods of measurement of axial length now routinely available due to recent advances in techniques. Whereas in developing nations ophthalmologists continue to rely on applanation and immersion ultrasound biometry in clinical consultation. But skilled doctors or technicians can usually obtain accurate Axial Length and IOL power measurements using these methods.

MATERIALS AND METHODS
In this prospective study, 196 consecutive patients of cataract (200 eyes) were enrolled in the Department of Ophthalmology. Each patient underwent axial length measurement by both applanation ultrasound A scan and optical low coherence reflectometry (By Lenstar). Keratometric readings were taken from Lenstar and Bausch Lomb manual keratometer. IOL power calculated using IOL calculation formula like SRK/T, Hoffer-Q and Holladay formula as per length of eyes. According to axial length of eye three groups were made; short (< 22 mm); normal (22-24.50 mm); and long (> 24.50 mm). All the data were collected, and statistical calculation was done using Microsoft Office Excel (2007). The mean, Standard Deviation (SD), standard error of the mean, Bland-Altman plot, Pearson’s correlation coefficient (r) calculated. With the help of linear regression, correlations were assessed between two different methods. Student ‘t’ test was used to compare data. P-value of less than 0.05 was statistically significant. Scatter diagram and Pearson’s correlation coefficient were used to analyse the correlation between the axial length and IOL power calculation by optical A scan biometry and manual A-Scan ultrasound. Bland-Altman plot were used for the analysis of agreement between graph of the ratios and readings measured by the two methods plotted against the means for the pairs of measurements. The upper and lower limits are connected with horizontal straight lines for the 95% confidence interval.

RESULTS
The study sample comprised of 196 consecutive patients (200 eyes), of which 92 were females and 114 were males. The majority of patients in the study were age group 40 - 59 years, i.e. 61 Males (52.5% of total male), 49 Females (58.2% of total female) (Table 1).

Both eyes of 4 patients were included in the study. Mean age of patients was 48.47±12.98 years (Range 14 - 78 years). The mean axial length calculated by optical system (Lenstar) was 23.02±1.00 mm (Range 19.91 - 27.27 mm) and by ultrasound A scan was 22.93±1.03 mm (Range 19.74 - 27.21 mm) (Table 2). The Mean Keratometric reading for optical system (Lenstar) was 44.75±1.70 D and for manual method by Bausch and Lomb Keratometer was 44.52±1.66 D.

Table 2. Comparison of Axial Length with Ultrasound A Scan and Optical A Scan

In the Graph (Figure 1) measurement by ultrasound A scan and optical biometry are stratified according to axial length. The differences in the mean axial length by the two methods are statistically non-significant; however, differences in the measurement are more for short eyes.

Figure 1: Comparison of axial length with ultrasound A scan and optical A scan.

Figure 2. Bland-Altman Plot of the Agreement in Axial Length with Ultrasound A Scan and Optical A Scan
The above Fig. indicates that 95% of all differences were within two standard deviations from mean differences (0.0869±0.038 mm, i.e. between 0.0096 mm and 0.1641 mm).

Image: Figure 3. Regression Line between Axial Length Measurement between Ultrasound A Scan and Optical A Scan

In the Graph (Figure 3) Pearson’s correlation coefficient ‘r’ is 0.999, which denotes strong correlation of axial length between optical system and ultrasound A scan.

**DISCUSSION**

A strong agreement between different methods is required, so that it can be used alternatively.[5] The Mean difference in axial length of optical system (Lenstar) and Ultrasound A scan was 0.087±0.039 mm, which is statistically insignificant (p value = 0.19). However, differences in axial length measurement were more when compared for hypermetropic (Short eyes) by two devices (Figure 1). The differences in mean IOL power between automated method and manual method was 0.43±0.38D, which is statistically and clinically insignificant (p value = 0.09). The Mean post-operative autorefract (Spherical equivalent) was 0.39±0.61D. The Mean post-operative autorefract in hypermetropic, emmetropic and myopic eyes were 0.39±0.70D, 0.38±0.61D and 0.35±0.52D respectively. No clinically significant differences were found when these findings were compared with mean post-operative refraction. The Bland-Altman plots (Fig. 2) 95% of all differences were within two standard deviations from mean differences (0.087±0.039 mm) that showed good relationship between two instruments. A difference of 0.087 mm converted to 0.21D, which is statistically and clinically insignificant. In our study, these differences were more when comparing measurements between instruments for small eyes, whereas the difference was not significant when compared with normal to long eyes.

The Mean difference calculated in axial length between optical system (Lenstar) and Ultrasound A scan was 0.087±0.039 mm, which was statistically and clinically insignificant. These findings are similar to study done by Chiseliță D et al 2011,[6] Salouti R et al 2011[7] and Nakhli et al 2014.[8]

**CONCLUSION**

In our study, there is no clinical difference in axial length measurement done by both optical biometry (Lenstar) and ultrasound A scan. Optical biometry in hypermetropic eyes gives better result in axial length measurement as compared to ultrasound A scan. Although, IOL power predicted by both Manual method and Automated method has no clinical difference in our study, Automated method gives more consistent result in eyes with different axial length. Consistent results were obtained by both the methods, because all the measurements were done by a 5-year experienced single ophthalmologist. Because of such experienced hand, we have got statistically insignificant difference in both the methods. Advantage of Automated method are fast measurement, non-contact technique, better patient coordination and comfort, operator independent, good for hypermetropic and myopic patient. But it also has disadvantages. It is not useful in dense media opacities like corneal scar, vitreous haemorrhage, mature cataract and thick PSC plaque and has high cost.
