UNILATERAL ABSENCE OF FIBULARIS TERTIUS: A CASE REPORT
Ankur Saxena¹, Shailendra Singh², Anita Tuli³, Sashi Raheja⁴

HOW TO CITE THIS ARTICLE:

ABSTRACT: INTRODUCTION: Fibularis tertius (FT) was formerly called as the peroneus tertius¹. FT muscle is a relatively small unipennate muscle found in the anterior compartment of the leg. It assists in dorsiflexion and eversion of foot². The FT muscle originates from the distal third or more of the medial surface of fibula, the adjoining anterior surface of the interosseous membrane and the anterior crural intermuscular septum. Thereafter, tendon runs beneath the superior extensor retinaculum, inferior extensor retinaculum and gets inserted on the medial aspect of the dorsal surface of the base of the fifth metatarsal. FT muscle is supplied by the deep peroneal nerve², 3, and 4. FT has been described as a part of the extensor digitorum longus (EDL) muscle in classical textbooks².

CASE REPORT: During routine dissection for the first MBBS students, we observed that the peroneus tertius was absent on the dorsum of the Right lower limb of a 50 years old, donated embalmed male cadaver in the Department of Anatomy, Lady Hardinge Medical College, New Delhi, India. Both the limbs were carefully observed and examined to differentiate the absence of FT muscle. There was no scar mark or sign of injury on the limb. The other muscles of the compartment were present normally with their normal anatomical features. The photographs of the dorsum of the foot were taken for proper documentation and for ready reference. The absence of the peroneus tertius is very rare and not found in literature. Usually, the peroneus tertius is involved in dorsiflexion and eversion of the foot.

DISCUSSION: With the adaptation to erect posture, the foot had to not only bear the weight but also maintain the balance of body, while walking and standing on uneven surfaces. The Peroneus are the
corner stone muscles that have evolved to perform this function. The FT muscle is absent in many primates with much variation in humans.\(^5\)

Peroneus tertius is highly variable in its form and muscle bulk but is rarely completely absent. It may be attached to the fourth metatarsal rather than the fifth\(^6\). It may be as large as the Extensor Digitorum Longus or it may be absent.\(^7\) The muscle might remain rudimentary or even absent in 4.4-10\% cases in humans.\(^8\) Similar study on Caucasian population showed its absence in 5-17\% of cases studied.\(^9\)

FT has been described as a part of the extensor digitorum longus (EDL) muscle in classical textbooks. Although closely associated with the EDL, the FT is not a member of the superficial layer of digital extensors (EDL), and in reality, it is a proximally migrated part of the extensor digitorum brevis (EDB) of the little toe.\(^8\) It represents the extensor digiti minimi (proprius) (pedis) with its insertion displaced to the base of the fifth metatarsal.\(^3\)

Peroneus Tertius may play a special proprioceptive role in sensing sudden inversion and then contracting reflexively to protect the anterior tibio-fibular ligament, the most commonly sprained ligament of the body.\(^9\)

The clinical importance of the Peroneus Tertius concerning prevention and treatment of ankle ligament injuries is low.\(^8\)

The insertion of the FT might play an important role in the causation of torsional stresses as observed in Jones fractures and stress fractures.\(^10\) Foot surgeons might use the FT muscle flap for transposition and also for correcting any laxity in the ankle joint.\(^11,4,\text{ and }12\) The absence of FT may misguide the surgeons in performing graft and transplant surgeries. Hence radiological imaging techniques must be performed to confirm the existence of the FT before planning any operation in foot. Thus the bilateral presence or absence of the FT may have a clinical and phylogenetic viewpoint that is highlighted in this case report.
