ABSTRACT

OBJECTIVE
To assess the outcome of primary closure of common bile duct following exploration for choledocholithiasis.

STUDY DESIGN
Descriptive case series.

MATERIAL AND METHODS
Clinical record of all patients of choledocholithiasis undergoing primary closure was retrieved. Patient's demography, intraoperative finding, operating time, hospital stay and operative complications were noted. SPSS version 11 used for analysis of data.

RESULTS
A total of 52 patients were studied, having male:female ratio of 1:6.4. Mean operating time was 100.3 minutes. The overall complication rate was 5.76%. Average hospital stay was 7.40 days. None of the patients developed post-operative peritonitis. There was no mortality in our study.

CONCLUSION
Primary closure following CBD exploration is a safe and effective measure for CBD stone associated with low complication rate and faster recovery.

KEYWORDS: Common Bile Duct, Choledochotomy, Choledocholithiasis.

INTRODUCTION
JNIMS is a recently established Medical College in Manipur, eastern most state of India bordering Myanmar. This study was conducted in surgery unit III, JNIMS. Choledocholithiasis is a common biliary condition requiring invasive intervention. It is managed endoscopically, laparoscopically, traditional surgery, interventional radiology, extracorporeal shock wave lithotripsy or a combination of methods. Traditionally, Common Bile Duct (CBD) is closed over T-tube. But surgeons all over the world preferred T tube closure. Currently, primary closure of CBD has been described in literature to overcome these adverse consequences of T-tube. This study was designed to assess the outcome of primary repair of CBD in terms of operating time, duration of hospital stay and postoperative complications and feasibility of this recent technique in the setting of a recently established Medical College.

METHODOLOGY
This retrospective and prospective case series was conducted at the Department of Surgery, unit III of JNIMS, Imphal. Clinical records of all the patients who underwent open CBD exploration with primary closure between Feb 2010 to August 2015 were retrieved. USG Abdomen was repeated in our institute as a unit protocol for those patients who were evaluated outside JNIMS. In doubtful cases MRCP was done. All patients were operated through right subcostal incision. After cholecystectomy except in one case, supraduodenal choledochotomy was done and CBD explored. One patient underwent CBD exploration via cystic duct.

Primary closure of the CBD was first described by Halstead in 1917. But surgeons all over the world preferred T tube closure. Currently, primary closure of CBD has been described in literature to overcome these adverse consequences of T-tube. This study was designed to assess the outcome of primary repair of CBD in terms of operating time, duration of hospital stay and postoperative complications and feasibility of this recent technique in the setting of a recently established Medical College.
Stones were retrieved with Desjardin forceps and CBD irrigated with normal saline. Proximal and distal patency were checked in all cases. Rigid nephroscope was used to visualize clearance of stone in few cases. Flexible choledochoscope was used to check for complete clearance and patency of both proximal and distal bile duct from February 2015. Choledochotomy was closed primarily using 3-0 vicryl in all cases. A subhepatic drain was kept in all cases, which was removed when there was less than 50ml serous fluid. All patients were routinely given IV third generation cephalosporin for 3 days and converted to oral antibiotic as required. Patient’s demographics (Like age and gender), operative time, duration of hospital stay, and postoperative complications including bile leakage, biliary peritonitis, and postoperative jaundice were recorded on a proforma. The data was compiled and the results tabulated using SPSS (Version 11, 2002, SPSS Inc., Chicago, IL, USA).

EXCLUSION CRITERIA
Those patients with hepatolithiasis, CBD diameter less than 12mm, who had h/o acute pancreatitis and suppurative cholangitis in the past were excluded from the study.

RESULTS
A record of 52 patients was retrieved who underwent open choledochotomy for ductal stone followed by primary closure. Fifty one patients had secondary stones and one patient had primary CBD stone presenting 25yrs. after cholecystectomy. There were 07(13.46%) males and 45(86.53%) females. The male-to-female ratio was 1.6:4, the ages of the patients ranged from 23-80 years with mean 45.53 years. Majority of patients have single stone, 12 patients have 2 stones and 3 patients have 3 or more stones. Operating time ranged from 86 minutes to 116 minutes. Before procuring choledochoscope for the institute, nephroscope was used to see for stone clearance. Subsequently, when choledochoscope become available in February 2015, it has been used routinely for all the cases operated. Average operating time was 100.93 minutes. Drain was removed most commonly between POD 5 and 7.

One patient had drain removed on POD10; she had prolonged ileus and another two on POD12 and POD13, both of whom had transient bile leak. Hospital stay range from 7 days to 16 days. Average hospital stay was 7.40 days. Overall complication rate was 5.76%. Transient bile leak was observed in two patients and one patient had prolonged ileus. None of our patients developed post-operative peritonitis. No patients required operative intervention for any of the complications. There was no mortality in our study.

DISCUSSION

JNIMS is a recently established Medical College in Manipur situated in the eastern border of India. There is no facility for ERCP and laparoscopic CBD exploration in JNIMS. Choledocholithiasis have been managed traditionally with T-tube closure or more recently with minimally invasive procedure like laparoscopic CBD exploration or with help of ERCP. T-tube drainage of the common bile duct is performed for the following reasons (Williams 1994) (a) Post-operative decompression of the common bile duct (If outflow obstruction occurs) (b) Post-operative visualization of common bile duct (c) Availability of a T-tube to extract common bile duct stones with a Burhenne steerable catheter (Burhenne 1973). However, the use of T-tube is not without complications. It is associated with peritubal leakage, excess bile drainage, electrolyte imbalance, peritubal cellulitis, sepsis, necrotizing fasciitis, post-T-tube removal bile leakage etc.10,11

This study showed no major morbidity associated with primary repair of bile duct after supraduodenal choledochotomy for choledocholithiasis. Moreover, this technique carried shorter operating time and duration of hospital stay. Zhang et al noticed 28.6% of complications rate associated with T-tube in contrast to 11.1% in whom primary repair was performed.12 Biliary complications are considered to be the major consequence after primary repair of CBD; however, their overall frequencies are much less than that of T-tube closure. Ahmad and Colleagues observed 22% and 8.9% of these complications in T-tube and primary closure groups respectively.13 Ambreen et al noticed one (6.3%) patient of bile leakage that subsided conservatively, which is comparable to this study. None of the patients in this study experienced postoperative jaundice and biliary peritonitis. This is comparable to the study conducted by Ambreen and associates.14 However, Perez et al reported biliary peritonitis after removal of T-tube.15

As a result of postoperative complications and long placement of T-tube till removal, duration of hospital stay gets prolonged. This forced surgeons to move towards primary repair technique that have been advised in literature. In this study, mean duration of hospital stay was 7.40 days, which is nearly comparable to the study conducted by Decker et al. The hospital stay was significantly longer in the T-tube group in three trials (Payne 1986; Williams 1994; Marwah 2004).16

The mean operating time in our study was 100.93 minutes, comparable to the study by Ha and Colleagues (95 minutes).17 Williams et al. (Williams 1994) found no significant difference in the operating time between the two groups (median operating time in both groups=120mins). Marwah et al. (Marwah 2004) reported a significantly lower operating time in the primary closure group compared to the T-tube group (Mean 87.8 versus 116.7 minutes, P< 0.001).18

This study is distinctive in approach, but has a limitation of being a descriptive analysis. This study shows the possibility of primary bile duct closure without putting T tube and is another good alternative where laparoscopic CBD exploration and/or ERCP is not available as has been shown by some other authors too. To correlate the complications and further comparison between the two treatment options, randomized clinical trials will be needed to strengthen the scientific evidence in favour of primary closure.

CONCLUSION
Primary closure of CBD is a safe and effective measure associated with low complication rates. It can be done in most of the cases of choledocholithiasis even in the setting of a very limited resource.
