A RARE CASE REPORT OF PYOGENIC LIVER ABSCESS CAUSED BY SALMONELLA ENTERITIDIS

ABSTRACT

BACKGROUND
Salmonella enteritidis is one of the most important serovars transmitted from animals to man and a serovar most commonly reported worldwide. Although infection with S. enteritidis is limited to the intestinal tract, under certain circumstances it may cross the mucosal barrier, disseminate and get established as some localized infectious focus. Although cited as a very uncommon cause, S. enteritidis may involve the liver and evolve into an overt abscess. Pyogenic liver abscess by a gas forming organism like S. enteritidis usually follow a fulminant course. Associated morbidity and mortality is high unless immediate therapeutic interventions are initiated.

KEYWORDS
Salmonella enteritidis, Pyogenic Liver Abscess, Gas Forming Organisms.

INTRODUCTION
All tissues and organs are susceptible to Salmonella and may manifest in a variety of clinical entities depending upon the site of localization. Localization of systemic infections is usually associated with predisposing conditions such as malignancy, diabetes, sickle cell disease, immunosuppression, structural abnormalities, etc. Perhaps 1% of enteric infections with non-typhoidal Salmonella result in bacteraemia. Pyogenic Liver Abscess (PLA) is one of the common liver pathologies and data from different sources place the incidence rate from 1.1 to 17.6/1,000 individuals. Salmonella is one of the well-known causes of liver abscess.

At least four Salmonella serovars, viz. typhi, paratyphi A, Enteritidis and infantis have been identified as causative agents of liver abscess. Here, we report a case of liver abscess caused by Salmonella enterica serovar enteritidis in an immunocompetent male. This organism being prolific fermenter, produces a large amount of gas at the site of localization and contributes significantly to increased morbidity and mortality. Prompt diagnosis and immediate therapeutic intervention is required in minimizing the injury to the patient.

CASE REPORT
A 28-year-old male was admitted to the Medicine Department of our hospital with 1-week history of high-grade fever with chills and rigors, moderate abdominal pain and vomiting. Patient gave history of diarrhoea and pain abdomen about 1 month before reporting to the hospital. There was no history of diabetes or tuberculosis in the past.

On examination he was conscious, febrile (Temperature-39°C), pulse rate was 160/min and blood pressure was 90/60 mmHg. He had pallor. There was no icterus. Per abdomen examination elicited tenderness in the right hypochondrium and epigastric region. Liver was palpable about 6 cm below the costal margin. Rest of the systemic examination was within normal limits. Routine haematological investigations revealed haemoglobin 8 g%, total leucocyte count-17,000/cumm (Polymorphs 75%, Lymphocytes 20%, Monocytes 2%, Eosinophils 3%) and platelet count of 2.2 lacs/cumm. Alkaline phosphatase was borderline elevated to 240 IU.

Other liver function tests, renal function values and serum electrolytes were within reference ranges. Serology for HIV, hepatitis B virus and hepatitis C virus were non-reactive. Widal test and IgM leptospira were negative. Ultrasonography of the abdomen showed mild ascites and enlargement of the liver with features suggestive of abscess involving segment VI and VII, measuring 8.5 cm x 8.5 cm x 8 cm and volume 320 cc. The patient was empirically started on intravenous vancomycin, monocet and metronidazole. But patient developed respiratory distress and his condition deteriorated further. Respiratory examination showed decreased air entry and crepitations in the right lower lobe. X-ray chest showed right-sided pleural effusion. Contrast enhanced CT scan abdomen revealed a large liver abscess in the right lobe communicating with the pleural cavity of size 8.5 cm x 8.5 cm x 8 cm. Ultrasound guided liver aspiration was done. About 35 mL of pus was aspirated and sent for microbiological investigations.

The pus sample was processed as per standard microbiological techniques. Wet mount of pus was negative for trophozoites of Entamoeba histolytica. Gram smear showed Gram-negative bacilli along with pus cells. Ziehl-Neelsen stain was negative for acid fast bacilli. On blood agar, 2-3 mm diameter non-haemolytic colonies and on MacConkey agar, non-lactose fermenting colonies were obtained. The isolate was identified as S. enterica subspecies enterica serovar enteritidis on the basis of biochemical reactions and further confirmed by agglutination test with specific antisera.

It was found to be susceptible to ampicillin, cotrimoxazole, third generation cephalosporins and ciprofloxacin by Kirby Bauer disc diffusion method. Blood and urine cultures were sterile. No pathogenic organism was grown in stool culture. For pleural effusion, pleural tapping was done and intercostal drain was inserted. Pleural fluid
also grew S. enteritidis with the antibiotic pattern compatible with the isolate from liver abscess. Treatment was changed accordingly. Metronidazole was stopped and ofloxacin added. However, the condition of the patient continued to deteriorate. He developed septicemia shock and succumbed to his illness after 5 days of admission.

**DISCUSSION**

The three major forms of hepatic abscess based on aetiology are pyogenic, amoebic and fungal. Most common pathogens of the pyogenic hepatic abscesses are *Escherichia coli*, *Klebsiella pneumoniae*, *Bacteroides*, *Enterococci*, *Streptococci* and *Staphylococci*. Among gas forming PLA, *K. pneumoniae* is the most frequently cultured organism. PLA due to *Salmonella* species is not that common and low incidence of hepatic manifestations may be explained by the phagocytic activity of its well-established reticuloendothelial system.

Soni et al. have also commented on the low frequency of abscess formation in *Salmonella* infections. Of all the serovars associated with hepatic abscess, Enteritidis is of special concern because of its potential to form gas from carbohydrates. It produces the formic hydrogen lyase, which converts formic acid a product of carbohydrate fermentation into CO₂ and H₂. The accumulated gas causes impaired transportation of gases and nutrients in the local tissues, promotes tissue destruction and results in abscess. In our case, S. enteritidis which produces a large amount of gas was the causative agent of PLA. In such a case, mortality is as high as 27.7% when compared with the 14.4% mortality in non-gas forming group. Hence, prompt recognition and appropriate treatment is crucial for the management of patient.

Pyogenic liver abscess due to enteritidis have been reported with pre-existing hepatobiliary diseases such as choledolithiasis, amoebic abscess, echinococcal cysts, intrahepatic haematoma, hepatocellular carcinoma, etc. However, in this case no such pre-existing condition was present. Furthermore, *Salmonella* liver abscess is mostly seen in the immunocompromised state, while our case was an immunocompetent adult male. Common presentations of PLA include abdominal pain, fever, chills, nausea and vomiting and a general feeling of illness. Blood culture was sterile in this case. The likely source of the liver abscess in our patient could be secondary to the seeding of infection from the transient portal bacteremia or infection localized in the gall bladder could have travelled to the liver parenchyma. Pyogenic abscesses can be single or multiple.

But *Salmonella* abscesses like amoebic abscesses are predominantly solitary and located in the right lobe. Ultrasonography and other imaging studies have wonderful sensitivities to pick up abscess pathologies, but microbiological diagnosis is absolutely essential to establish a causal relationship and strategizing further therapeutic plans. Here, despite the fact that treatment was immediately modified to confirm to the antimicrobial sensitivity pattern of enteritidis, patient could not be saved probably because the patient had already landed into septicemia.

Organisms like S. enteritidis, which restrict to the intestinal tract and behave in a predictable manner when affect extraintestinal sites like liver, may cause fatal damage as seen in this case. Such cases warrant the scientific community to take a relook at the treatment algorithms. Such cases also need to be diagnosed at the initial stage and be kept on surveillance for the development of morbidity conditions like liver abscess. This is important in geographical areas where *Salmonella* infections are endemic.

Enteritidis is one of the rare causes of liver abscess. But in endemic geographical locations, this should be considered in the differential diagnosis, especially in cases with a proven history of intestinal illness. Liver abscess caused by gas forming organisms carry a high mortality and warrant immediate therapeutic intervention, which may include decisive surgical management and dedicated Intensive Care.
