ABSTRACT

BACKGROUND
Tibia is a large bone of the body and one of the principal load bearing bones in lower extremity. Non-operative treatment of tibial fractures is associated with a high prevalence of malunion, stiffness of the joint & poor functional outcome. Intramedullary interlocking nailing is a technique which allows stable reduction and early mobilisation. The assessment of autonomic functions is an important part of the evaluation of peripheral and central nervous system.

The Aim of the study was to assess the end results and autonomic functional status in tibial fracture treated by early interlocking intramedullary nailing in young adults.

MATERIALS AND METHODS
56 patients in the age group of 18-40 years who presented with diaphyseal fractures of tibia were studied from November 2013 to October 2015 (2 years). Average followup was 7 months. Immediate heart rate response to standing (30:15 R-R ratio) was done to assess the parasympathetic function. Cold Pressor Response (CPR) was done to assess the sympathetic function.

RESULTS
The average duration of partial weightbearing was 3 weeks. The average duration of full weightbearing was 14 weeks. The average time of healing was 17 weeks. All patients except 2 showed normal parasympathetic function (30:15 R-R ratio). All patients except 2 showed normal sympathetic function (Cold Pressor Test).

CONCLUSION
Due to lack of information about autonomic functions of the patients before fracture and small sample size, further studies are needed to assess changes in autonomic functions of the patient following this procedure. Because of the high union rate and low infection rate, we consider closed interlocking nailing as the best mode of treatment for diaphyseal tibial fractures.

Tibia, Interlocking, Nailing, Autonomic.

HOW TO CITE THIS ARTICLE: Das TK, Debnath A. Study of the end results and assessment of autonomic functional changes following early management of diaphyseal fracture of tibia by interlocking nailing in young adults. Dent. Sci. 2017;6(90), DOI: 10.14260/jemds/2017/1382

BACKGROUND
Tibia is a large bone of the body and one of the principal load bearing bones in lower extremity. Fractures can cause prolonged morbidity, extensive disability unless treatment is appropriate.¹ The annual incidence of tibial shaft fracture is 26 per 10000 individuals. Males are more commonly affected than females.² Non-operative treatment of tibial fractures is associated with a high prevalence of malunion, stiffness of the joint and poor functional outcome. Plating resulted in higher incidence of non-union, infection and fixation failure.³ Advantages of intramedullary nailing⁴ are closed reduction and preservation of periossteal blood supply, early mobilisation of knee and ankle joint and early bone union. Locked intramedullary nailing is currently considered the treatment of choice for most tibial shaft fractures.⁵ The assessment of autonomic functions is an important part of the evaluation of peripheral and central nervous system. The autonomic function tests are reliable, reproducible, simple, quick to carry out and all non-invasive. Autonomic function tests are classified as parasympathetic and sympathetic function tests.⁶ The study was done to assess the end results and autonomic functional status in tibial fracture treated by early interlocking nailing, to study the rate and quality of bony union, complications of interlocking nailing in tibia and to determine the autonomic functional improvement after the procedure.

MATERIALS AND METHODS
The study was done among 56 patients of 18 to 40 years age group, who presented with diaphyseal fractures of tibia, closed fractures, open type-I fractures, segmental fractures, comminuted fractures in Department of Orthopaedics of Agartala Government Medical College and Hospital from November 2013 to October 2015 prospectively. Patients were followed up for a period of 4 months to 2 years (average followup was 7 months). Patients with open fractures type-II and type-III, associated with head injury, pathological
fractures were excluded from this study. Finally, 56 patients were included in this study as 12 patients were lost to followup. Patients were followed up every 4 weeks, 8 weeks, 12 weeks, 16 weeks, then every 8 weeks. Clinical, Radiological and autonomic functional assessment was done in each followup.

**Autonomic Function Tests**

1. To assess the parasympathetic function: Immediate heart rate response to standing (30:15 R-R ratio).
2. To assess the sympathetic function: Cold Pressor Response (CPR).

**Immediate Heart Rate Response to Standing (30:15 R-R Ratio):**

Patient was asked to lie supine quietly on a couch for 15 minutes with Sphygmonanometer & ECG leads attached. The resting ECG (lead II) was recorded and the baseline heart rate and the resting BP also measured. Then the subject was asked to stand and remain motionless. A continuous ECG was recorded for 1-3 minutes. The BP was measured at 1 and 3 minutes after standing. HR was noted at the 15th and 30th beat after standing. 30:15 R-R ratio was calculated and compared with the normal value.

**Cold Pressor Response**

The patient was asked to sit on a chair and the baseline BP was recorded. The subject was asked to immerse his hand in cold water maintained at 40-60 C; the BP was recorded from the other arm at 30 sec. interval for a period of 2 minutes. After 2 minutes the subject was allowed to remove the hand. Maximum increase in systolic and diastolic BP was determined and it was compared with the normal. The end results were assessed on the basis of Alho and Ekeland criteria.

**This Criteria Considers Six Aspects**

- Tibial mal-alignment and shortening.
- Range of knee motion & extensor lag.
- Range of ankle motion.
- Foot Motion.
- Pain in limb.
- Swelling.

**RESULTS**

We had studied 56 patients until final followup. Majority of the patients (40%) were from 36-40 years age group followed by 31-35 years age group (32%). Fractures of tibia were found to be more common in males i.e. 44 (78%) as against females 12 (22%). Right-sided tibia fracture was seen among 42 patients (75%). Road traffic accidents were found to amount for most of the injuries (44, 78%) and fall from height to 22% cases. Most of the fractures requiring fixation were either in the distal third of the shaft (28, 50%) or middle third (20, 36%). The average duration of partial weightbearing was 3 weeks (range 2 to 4 weeks). The average duration of full weightbearing was 14 weeks (range 12-16 weeks). The average time of healing was 17 weeks. 20 (36%) fractures healed in 16 weeks, 28 (50%) in 18 weeks, 6 (17.24 %) in 20 weeks and 2 (3.45 %) in >20 weeks. Superficial wound infection was encountered in 4 patients. No patient developed deep infection. In 8 cases, there was delayed union so dynamisation was done. Fractures healed satisfactorily. Patients developed anterior knee pain. 82.14% of patients had excellent results, 14.27% showed good results. No patient had poor results.

**DISCUSSION**

Majority of the patients in this study were in the age group of 35-40 years. Ekeland et al (1988), in their study series of 45 patients noted the mean age of patients to be 35 years. Hooper et al (1991) showed that the incidence of fracture had male preponderance (82%). In our study, incidence in male was 78.5%. In our study, 44 patients (78.5%) of the tibial diaphyseal fractures occurred due to road traffic accidents. Majority of cases were the motorists. Lawrence Bone et al (1986) reported a 90% incidence of road traffic accidents in tibial shaft fractures. In our series, the anatomical location of the fracture was in the distal-third of the shaft of tibia in 28 (50%) patients, followed by the mid third in 20 (36%).

Court Brown et al (1995) showed 44% were middle third fractures. The shaft of the tibia is the narrowest at the junction of its middle and inferior thirds, which is the most frequent site of fracture. Larsen et al studied 45 patients withreamed interlock nail in whom average time to fracture healing was 16.7 weeks and had two malunions while in our study healing time was 17 weeks with no malunion. In our series, majority of fractures united within 20 weeks (48 patients). Anglen et al (1995) showed average union time of 22.5 weeks, Lawrence B Bone et al (1995) reported average time of union 19 weeks. In our series, 4 patients (7%) had superficial wound infection of the proximal incision site. This responded to the oral antibiotics and dressings. We had no case of broken or bent nail. No case of bent or broken screw reported. We had no compartment syndrome, lateral popliteal nerve palsy or fat embolism. Few patients experienced anterior knee pain, pain at fracture site and locking bolt in treatment phase, most of them recovered after sound union, physiotherapy and analgesics.

The assessment of autonomic function is an important part of the evaluation of the peripheral and central nervous system.
system. Abnormalities of autonomic function lead to different clinical entities like orthostatic hypotension, sexual dysfunction, diarrhoea, incontinence, dryness of mouth and so on. Autonomic function tests are performed to confirm the clinical diagnosis of autonomic neuropathies and to assess the intactness of the sympathetic and parasympathetic pathways.

We examined both sympathetic (Cold pressor test) and parasympathetic (30:15 R-R ratio) system. Only 2 patients (3.6%) showed abnormal sympathetic and parasympathetic function. Those patients were known diabetics. Before injury no data about autonomic system was available, so those patients might have had poor autonomic function before fracture. Ghai C L stated that in some normal persons there might be no significant rise in BP after cold pressor test. Mourtet al13 said that further studies are needed to explain why healthy subjects react differently to the CPT and if this has potential clinical implications.

CONCLUSION
The incidence of tibial diaphyseal fractures in young adults has increased significantly during recent decades and this tendency will probably continue in the near future due to high energy trauma. The goal of the treatment of these fractures is stable fixation, which allows early return to function. Due to lack of information about autonomic functions of the patients before fracture and small sample size, further studies are needed to assess changes in autonomic functions of the patient following this procedure. Because of the high union rate and low infection rate, we consider closed interlocking nailing as one of the best mode of treatment for diaphyseal tibial fractures.
