PRESENTATION OF CASE
A 59-year-old gentleman presented with the chief complaint of generalised abdominal distension for the last 2 years. It had achieved an uncomfortable size, which was disturbing his day-to-day activities. It was not associated with any pain, obstructive or compressive symptoms and no history of low-grade fever, night sweats and anorexia or weight loss.

Patient’s nutritional status was good, had mild pallor and bilateral pedal oedema.

On examination, the abdomen was found to be hugely distended with an inverted umbilicus (girth 160 cm). No venous engorgement or pigmentation were noted. A diffuse firm lump was palpated in all quadrants of the abdomen, non-tender, non-mobile, no organomegaly and no evidence of ascites. Routine investigations were within normal limits.

CT scan and USG revealed a lobulated mass with predominantly fat content and areas of soft tissue occupying most of the abdomen. It had fine septations, tiny calcifications measuring 39.4 by 36.9 by 29.1 cm (Fig 1, 2).

DIFFERENTIAL DIAGNOSIS
The possible differential diagnoses of the lump is-

a. Retroperitoneal sarcoma.
b. Mesenteric cyst.
c. Omental cyst.

CLINICAL DIAGNOSIS
Based on the clinical findings and investigations, a diagnosis of a retroperitoneal neoplasm was made.

DISCUSSION OF MANAGEMENT
DJ stenting of both ureters was done 3 days before the operation.

The abdomen was opened by a midline incision. After opening the peritoneum, a solid, yellowish, encapsulated lesion (15 * 10 * 10 cm) was seen in the central part of abdomen along with 2 - 3 similar larger masses (30 * 15 * 15) beneath it with very evident cleavage planes (Fig 3). The small bowel was pushed towards the right hypochondrium.

The lesions were separated from the colon, kidney, ureter, inferior vena cava and abdominal aorta by very evident cleavage planes. No invasion of any major organ was noted. Mesentery was free. The capsule had adherence to the retroperitoneal tissue and had small calibre vessels on its surface.
After the major 3 lesions were removed, smaller masses were dissected out. Total weight was 15.5 kg (Fig. 4). Postoperative period was uneventful.

**PATHOLOGICAL DISCUSSION**

It showed mature adipose tissues arranged in lobules with intervening septae of vascularised collagenous tissue (Fig. 5). Secondary changes in the form of haemorrhage and spindle cells were also noted.

**DISCUSSION**

The exact prevalence of lipomas is an enigma due to rather asymptomatic nature of the lesion. Intra-abdominal lipomas are the rarest of them all.\textsuperscript{1,2} Such tumours occur commonly in the age group above 50 yrs. and have been seen more among women.\textsuperscript{3}

Literature search reveals around 30 such documented cases. Pathogenesis is rather unknown with possible factors could be obesity, diabetes mellitus, elevation of serum cholesterol, radiation, familial tendency and chromosomal abnormalities.\textsuperscript{4,5}

Malignant change of lipoma to liposarcoma is almost never seen. These benign lesions may grow to large proportions and numbers, but generally do not mutate.\textsuperscript{6} Deep lipomas are noted only when they grow in larger proportions to their size, but clinical manifestations are rather rare.

Ultrasonography depicts these intra-abdominal lipomas as well-defined homogeneous, echogenic masses. Computed tomography reveals these masses with low attenuation similar to adipose tissue.\textsuperscript{7}

In most of the cases complete surgical excision is easily performed, because the capsule that surrounds the tumour presents a very evident cleavage plane.\textsuperscript{8}

Liposarcoma of low-grade malignancy (Grade 1) can have a similar appearance and are denominated lipomas like.\textsuperscript{9} As liposarcoma is a possibility in these lesions, so a complete surgical excision is the treatment of choice.\textsuperscript{10} Recurrence rate is less than 5% and is seen only due to incomplete excision of the mass.\textsuperscript{8}

Other possible diagnoses like lipoblastoma, lymphangioma, liposarcoma or lymphangiolipoma should be considered.\textsuperscript{9}

**FINAL DIAGNOSIS**

The final diagnosis of the case was that of a giant intra-abdominal lipoma.
