ABSTRACT

BACKGROUND
Lichen planus is an idiopathic subacute or chronic inflammatory disease of the skin, mucous membranes, and nails. We studied the clinicopathological profile of 50 cases of Lichen planus in Osmania General Hospital from September 2010-April 2012.

METHODS
A total of 50 cases Lichen planus attending DVL OPD at OGH were studied. Clinical features like age, sex, type of Lichen planus, location were recorded in the case record form. Histological features of Lichen planus were studied.

RESULTS
Out of 50 cases, majority (46%) were of Generalised Lichen Planus. Majority of cases were in the age group of 20-40 years and showed Male preponderance. Most commonly, violaceous lesions occurred in Lichen planus pigmentedus and both violaceous and pigmented in Lichen planopilaris.

CONCLUSIONS
Among the various types of Lichen Planus, Generalised Lichen Planus is the commonest (46%). Other clinical variants like Hypertrophic, Mucosal (Oral and genital), Linear, Actinic, Lichen Planus Pigmentosus, Follicular, Palmoplantar, and Vesciculobullous were seen less common. Most of the components of Lichen Planus on histopathology exhibit apoptosis of individual cells with formation of colloid bodies, hydropic degeneration of basal cells, melanin incontinence, and band-like inflammatory infiltrate at the dermoepidermal junction.

KEYWORDS
Lichen Planus, Clinico-histopathological.

INTRODUCTION
Lichen planus was first described in 1869 by Erasmus Wilson. The primary lesion were papules and had a resemblance to the Lichen fungi on trees. It is an idiopathic, subacute, or chronic inflammatory disease of the skin characterized by pruritic, purple, plane topped, polygonal papule that affects skin, mucous membranes, hair follicles, and nails. Exact pathogenesis of Lichen planus is still unclear. Several hypotheses have been made regarding its aetiology including genetic, infective, psychogenic, and autoimmune factors (Suagerman et al11 Sontheimer, 2009). Recent studies provide evidence that autoreactive cytotoxic T lymphocytes are the effector cells, which cause degeneration and destruction of keratinocytes causing keratinocyte apoptosis (Sontheimer, 2009). The lesions may result in longstanding residual hyperpigmentation especially in dark skinned patients. The slightly scaly surface is typically crossed by delicate white lines known as Wickham's striae. LP has characteristic clinical and histopathological features, which make the diagnosis relatively easy. The following are the clinical variants of LP.

1. Based on Configuration: Annular and Linear LP

CLINICAL FEATURES
Most cases of lichen planus (LP) are insidious. Lesions usually develop on flexural surfaces of the limbs, such as the wrists. After a week or more, a generalized eruption develops with maximal spreading within 2-16 weeks. Pruritus is common in Lichen planus, but varies in severity depending on the type of lesion and the extent of involvement. Hypertrophic lesions are extremely pruritic.

Oral lesions may be asymptomatic or have a burning sensation or they may even be painful if erosions are present. In more than 50% of patients with cutaneous disease, the lesions resolve within 6 months and 85% of cases subside within 18 months. On the other hand, oral Lichen planus had been reported to have a mean duration of 5 years. Large, annular, hypertrophic lesions, and mucous membrane involvement are more likely to become chronic.
In addition to the cutaneous eruption, Lichen Planus (LP) can involve the mucous membranes, the genitalia, the nails, and the scalp. The clinical presentation of Lichen planus has several forms: actinic (in sun-exposed areas), annular, atrophic, erosive, follicular, hypertrophic, linear, pigmented, and vesicular/bullous. The papules are violaceous, shiny, and polygonal; varying in size from 1 mm to greater than 1 cm in diameter (see the image below). They can be discrete or arranged in groups of lines or circles. Characteristic fine white lines called Wickham striae are often found on the papules.

Mucous membrane involvement is common and maybe found in patients who do not have skin involvement. Lesions are most commonly found on the tongue and the buccal mucosa; they are characterized by white or gray streaks forming a linear or reticular pattern on a violaceous background. Oral lesions are classified as reticular, plaque like, atrophic, papular, erosive, and bullous. Ulcerated oral lesions may have a higher incidence of malignant transformation in men, but this observation maybe confounded by other factors such as smoking and chewing tobacco. Lesions may also be found on the conjunctivae, the larynx, the esophagus, the tonsils, the tympanic membrane, the bladder, the vulva, and the vaginal vault; throughout the gastrointestinal tract; and around the anus.

Genital involvement is common in Lichen planus. Typically, men develop annular lesions on the glans. Wickham striae may also be observed on these lesions. Vulvar involvement can range from reticulate papules to severe erosions. Dyspareunia, a burning sensation, and pruritus are common in women. Vulvar and urethral stenosis may be a complication. It is estimated that more than 50% of women with oral lichen planus also had undiagnosed vulvar involvement. Lesions can involve the mucous membranes, the genitalia, the nails, the scalp, the mucous membranes, and covered areas. Lesions are characterized by nummular patches with a hypopigmented zone surrounding a hyperpigmented centre.

Lichen Planus Pigmentosus: This is a rare variant of Lichen planus, but can be more common in persons with darker-pigmented skin such as Latinos or Asians. It usually appears on face and neck. Some believe it is similar to or the same as erythema dyschromicum perstans (i.e., Ashy dermatosis).

Lichen Planus Pemphigoides: This is a rare form of Lichen planus. Blisters subsequently develop on Lichen planus lesions. Clinically, histopathologically, and immunopathologically, it has features of Lichen planus and bullous pemphigoid, but it carries a better prognosis than pemphigoid.

Differential Diagnosis
- Dermatological manifestations of graft vs host disease.
- Guttate psoriasis.
- Lichen nitidus.
- Lichen simplex chronicus.
- Paediatric syphilis.
- Pityriasis rosea.
- Plaque psoriasis.
- Tinea corporis.

MANAGEMENT
Diagnostic Workup
- Laboratory Studies: Direct immunofluorescence study in Lichen Planus (LP) reveals globular deposits of immunoglobulin M (IgM) and complement mixed with apoptotic keratinocytes.
- Histopathological Examination: Typical papules of Lichen planus show the following features on histopathology.
Epidermal Changes
Compact orthokeratosis, wedge-shaped hypergranulosis, irregular acanthosis, colloid bodies, flattened rete ridges, liquefactive degeneration of basal layer, and Max Joseph's space.

Dermal Changes
Band-like infiltrate hugging the basal layer, perifollicular infiltrate, lymphocytes, plasma cells, eosinophils, and melanin incontinence.

TREATMENT

Medical Care
Lichen planus (LP) is a self-limited disease that usually resolves within 8-12 months. Mild cases can be treated with fluorinated topical steroids. More severe cases, especially those with scalp, nail, and mucous membrane involvement may need more intensive therapy.

Medical Treatment
The first-line treatments of cutaneous Lichen planus are topical steroids particularly class I or II ointments. A second choice would be systemic steroids for symptom control and possibly more rapid resolution. Many practitioners prefer intramuscular triamcinolone 40-80 mg every 6-8 weeks. Oral metronidazole has been shown to be an effective therapy for some patients.[1] Oral acitretin has been shown to be effective in published studies.[6] Many other treatments including mycophenolate mofetil at 1-1.5 g twice daily are of uncertain efficacy owing to the paucity of evidence. In a randomised double-blind study, sulfasalazine at up to 2.5 g/day for 6 weeks showed improvement in lesions (>80%) and pruritus (>90%) in patients with generalized Lichen planus.

For Lichen planus of the oral mucosa, topical steroids are usually tried first. Topical and systemic cyclosporine have been tried with some success,[7] however, a randomised double-blind study indicated that topical cyclosporine was a less effective, but much more costly regimen than clobetasol.[8] Newer topical calcineurin inhibitors have replaced topical cyclosporine for the treatment of Lichen planus. Other options include oral or topical retinoids. Even with these effective treatments, relapses are common.

Close monitoring of lipid levels is suggested for patients with Lichen planus who are treated with oral retinoid agents because a case control study found that the risk of dyslipidaemia in these patients is increased 2-3 fold.[9] In fact, according to a meta-analysis of 5,242 patients even those who did not receive retinoids might still have dyslipidaemia.

Patients with widespread Lichen planus may respond to narrow-band or broadband UV-B therapy.[10] Psoralen with UV-A (PUVA) therapy for 8 weeks has been reported to be effective. Risks and benefits of this treatment should be considered. PUVA is carcinogenic. Long-term risks include dose-related actinic degeneration, squamous cell carcinoma, and cataracts. A phototoxic reaction with erythema, pruritus, phytophotodermatitis, and friction blisters could occur.

UV-A therapy combined with oral psoralen consists of oral psoralen (0.6 mg/kg), 1-2.5 hours before ultraviolet light, which usually starts at 0.5-1 J/cm² and is increased by 0.5 J/cm² per visit. Use of topical ointment at the time of receiving UV-A treatment may decrease the effectiveness of PUVA. Precaution should be taken for persons with a history of skin cancers or hepatic insufficiency. Apremilast may be an effective treatment for Lichen planus, but double-blinded controlled trials are lacking.[11]

Complications
Malignant transformation has been reported in ulcerative Oral Lichen Planus (OLP).[12] Cutaneous hypertrophic lichen planus resulting in Squamous Cell Carcinoma (SCC) was reported in a series of 38 patients.[13] Pruritic and painful vulvar lichen planus has been a precursor to SCC in a small number of cases.

Infection, osteoporosis, adrenal insufficiency, bone marrow suppression, renal damage, hyperlipidemia, and growth restriction in children may occur due to medication adverse effects. Post inflammatory/residual hyperpigmentation may be a common marker after Lichen planus has subsided. Alopecia associated with Lichen planus is often permanent.

Hepatitis C virus infection may be present in 16% of Lichen planus patients. Additionally, a meta-analysis reported that hepatitis C virus seropositivity could be 6 times higher in oral Lichen planus patients than controls.[14]

Prognosis
The prognosis for Lichen planus is good as most cases regress within 18 months. Some cases recur. In Lichen planus, atrophy and scarring are seen in hypertrophic lesions and in lesions on the scalp. Cutaneous Lichen planus does not carry a risk of skin cancer, but ulcerative lesions in the mouth, particularly in men, do have a low rate of malignant transformation. However, the malignant transformation rate of oral Lichen planus is low (<2% in one report). Vulvar lesions in women may also be associated with squamous cell carcinoma.

Patient Education
Patients should be told about the self-limiting nature of Lichen planus. Because Lichen planus is not common, no large, randomised, controlled clinical trials have been conducted for therapy. Several treatments may need to be tried.

Patients should be told about the small likelihood of recurrence and the potential adverse effects from the various treatments offered.

Cutaneous LP has worldwide distribution with its incidence varying from 0.22% to 1% depending upon geographic location (Boyd and Neldner, 1991).[15] According to one study, LP represents 0.38% of all dermatology outpatients in India (Bhattacharya et al., 2000).[16] However, there is a paucity of Indian literature describing the clinicopathological profile of Lichen planus. Therefore, we conducted this study to document and analyse the clinicopathological profile of LP in Indian population.

MATERIALS AND METHODS
The study was conducted in the DVL Department, Osmania General Hospital from September 2010-April 2012. Retrospectively, we analysed all the cases of Lichen planus received in our department. A total of 50 clinically diagnosed Lichen planus cases were included for studying the clinical and histopathological aspects of Lichen planus. Clinical features like age, sex, duration of the lesion, type of Lichen planus, significant family history and personal history, history of associated diseases, and drug intake was taken and entered
in the proforma. After detailed general and local examination, the site of biopsy was selected. The selected patients consent was taken after explaining the details of biopsy procedure.

The biopsy is done on the lesion along with the surrounding area with a 4 mm punch biopsy specimens are stained with H and E and the histopathological features of Lichen planus were studied under a microscope. Each skin biopsy was subjected to systematic, critical interpretive assessments in sequence of epidermal changes like basal cell death or vacuolar change, varying thickness of different layers of epidermis. Decimal changes like interface dermatitis and composition of different cell types, focal or diffuse nature of the lesion, pigment incontinence along with appendageal involvement were noted. All these features were noted for comparison with clinical subtype.

**Statistical Analysis**

Fisher’s exact test was used to assess associations between various variables. All analyses were performed using SPSS software. A p-value of less than 0.05 was considered statistically significant.

Lichen planus - Flat topped violaceous papules with fine scale clinically and histopathology showing hyperkeratosis, irregular acanthosis, and band-like inflammatory cells.

Lichen planus - Generalised with Koebner’s phenomenon, histopathology showing basal degeneration and civatte bodies.
RESULTS
Out of 50 cases of Lichen planus studied, 23 (46%) cases were of generalised Lichen planus, 7 (14%) cases were of hypertrophic LP, 5 (10%) cases were of mucosal LP (Oral+genital), 4 (8%) cases were Actinic LP and Linear LP each. 3 (6%) cases were Lichen planus pigmentosus. 2 (4%) cases were Follicular LP. 1 (2%) case was palmoplantar and vesiculobullous type each. Out of 50 cases, 47 (94%) cases were clinically diagnosed and histopathologically confirmed. 3 (6%) cases were clinically doubtful and confirmed histologically. 27/50 (54%) were males and 23/50 (46%) were females with sex ratio of 1.17:1 (Male:Female). Majority of the patients of Generalised Lichen Planus, Hypertrophic LP, Mucosal LP, and Follicular LP were in the age group of 21-50 years.

The age range of the patients was from 5 to >50 years in males and females. All the cases (50) were divided into different subgroups based on clinical variants, age, and sex and the histopathological findings in epidermis and dermis were noted. In epidermis out of 50 cases, Parakeratosis was seen in 2 cases, Hyperkeratosis in 45 cases, Acanthosis in 42 cases, Spongiosis in 40 cases, Papillomatosis in 10 cases, Sawn-toothed rete ridges in 20 cases, Civatte bodies in 46 cases, Liquefactive degeneration of basal layer in 48 cases, and Max-Joseph’s space was seen in 6 cases. In dermis out of 50 cases, band-like configuration hugging the basal layer was seen in 48 cases, perifollicular infiltrate in 2 cases, mononuclear cells in all the 50 cases, plasma cells and eosinophils each in 1 case and melanin incontinence was seen in 46 cases.

DISCUSSION
This prospective study is done to assess the different types of Lichen planus, which were confirmed histopathologically. In our study, Generalised Lichen Planus was the most common type of LP. It was about 46%. Hypertrophic Lichen Planus was the next most common type accounting for 14% of cases. Mucosal Lichen Planus was seen in 10% of our cases with oral mucosal involvement in 8% of cases and genital mucosal involvement in 2% of cases. Next common variant in our study was Linear Lichen Planus and Actinic Lichen Planus both accounting for 8% each. Lichen Planus Pigmentosus was seen in 6% cases in our study. Follicular Lichen Planus was seen in 4% of cases, palmoplantar and vesiculobullous variants were seen 2% each in our study. Singh OP and Kanwar AJ (1976)17 found the incidence of various lesions clinically in North India as follows in comparison with our study.

Table 2

Coming to histopathological analysis in our study, the epidermal changes most evident in many cases were hyperkeratosis, acanthosis, civatte bodies, and liquefactive degeneration. Dermal changes most evident in many cases were band-like configuration, hugging basal layer, and the inflammatory cells were lymphocytes in all cases. Very few cases showed plasma cells and eosinophils. Pigment incontinence was very predominant in Actinic Lichen Planus. Epidermal hypertrophy was markedly seen in Hypertrophic variant.

In 1965, Ellis Francis19 did analysis of one hundred biopsies and recorded almost similar findings histopathologically.

CONCLUSION
In conclusion, our results indicate that among various types of Lichen planus, classical Generalised Lichen Planus is the commonest. Mucosal lesions in these cases were not seen in all cases. Other clinical variants like Hypertrophic, Mucosal (Oral and genital), Linear, Actinic, Lichen Planus Pigmentosus, Follicular, Palmoplantar, and Vesiculobullous Lichen Planus were seen less commonly.

The tie to pathological changes encompassed epidermal basal cell damage seen as apoptosis of individual cells with formation of colloid bodies, hydropic degeneration of the basal cells, melanin incontinence secondary to basal cell damage.
damage, and band-like inflammatory infiltration hogs the dermo-epidermal junction.

Most of the components of Lichen planus variants exhibit this reaction except for subtle difference that define the particular variant.

Recognition of these commonly encountered problems depends upon the familiarity of clinical presentation and the diagnosis can be confirmed histopathologically. Accurate diagnosis by histopathology also depends on the available clinical information.

Clinicopathological correlation is the key to providing optimal patient care.
