PRESENTATION OF CASE

A 3 years old male patient came to the Department of Radiodiagnosis, Assam Medical College, Dibrugarh, Assam with complaints of swelling over the right anterolateral chest wall associated with difficulty in breathing since 20 days.

On examination there is a soft, non-tender swelling in the anterolateral aspect of right chest wall (Figure 1). The patient was found to have absent breath sounds and dullness on percussion in the right lower lung field. Laboratory findings were normal. The patient was subjected to a chest x-ray, which showed a large homogenous opacity in the right hemithorax obscuring the right hemidiaphragm, right cardiophrenic angle and right heart border and displacing the mediastinum to the contralateral side (Figure 2). Patient then underwent CT scan examination of the thorax that revealed a huge fat density (-65 to -105 Hounsfield units) lobulated lesion with scattered areas of soft tissue density and septations in right hemithorax causing passive collapse of the underlying right middle and lower lobe with contralateral mediastinal shift. The lesion was protruding anterolaterally into the extrapleural space through the 6th and 7th right intercostal spaces (Figure 3). A provisional diagnosis of intrathoracic pleural lipoma was made.

DIFFERENTIAL DIAGNOSIS

Pleural lipoma, pleural liposarcoma.

PATHOLOGICAL DISCUSSION

The patient underwent right thoracotomy which revealed a lobulated, yellowish soft tumour which had a smooth surface. There was no adhesion between the tumour and the surrounding organs, and the entire mass was successfully resected. Histopathologic examination revealed an encapsulated tumour with abundant mature adipocytes without evidence of sarcomatous changes consistent with pleural lipoma (Figure 4).

Lipomas are benign mesenchymal neoplasm, commonly seen in adults. They account for approximately half of all soft tissue tumours and 80% of all benign fat-containing neoplasms. Conventional lipomas can arise in subcutaneous tissue (superficial lipoma), in deep soft tissue (deep lipoma) or on surface of bone (parosteal lipoma). However, intrathoracic lipomas are rare and can arise from the mediastinum, diaphragm, bronchus, lung or thoracic wall.[1,2]

Thoracic or pleural lipomas originate from submesothelial layers of parietal pleura and can extend into the subpleural, pleural or extrapleural space, and they exhibit slow growth. They can arise from the lateral wall as well from the mediastinal or diaphragmatic pleura.[3]

Lipomas can also be divided into two classes: (1) Hourglass or dumbbell lipomas that pass through intercostal space or the thoracic inlet as seen in our case; and (2) Purely intrathoracic lipomas.[4]
DISCUSSION OF MANAGEMENT

Most patients remain asymptomatic, but since lipomas are able to grow to a large size they may provoke compression symptoms. Symptoms such as dyspnoea and dysphagia due to local compression on adjacent structures, such as the trachea or oesophagus. CT allows a definitive diagnosis when it demonstrates a homogeneous fat attenuating mass (-50 to -150 Hounsfield units or HU) forming obtuse angles with the chest wall and displaces adjacent pulmonary parenchyma and vessels. The density may not be entirely uniform, because lipomas often contain fibrous stroma.

The management strategy for pleural lipomas is still controversial. An observation principle with clinical and radiological follow-up may be suitable for elderly patients and those in poor general condition, especially in the presence of small and asymptomatic lesion. However, surgical treatment is generally definitive and the incidence of recurrence is extremely low and essentially related to incomplete removal of the lesion.

CT scan plays a pivotal role in clarifying and characterising nonspecific findings of chest x-rays and helps in differentiating pleural from extrapleural lesions. Moreover, CT helps in knowing the nature and extension of the lesion and helps in its precise characterisation and diagnosis. Although, pleural lipoma is a rare benign neoplasm, but when large it can cause severe compression symptoms and give rise to complications. Moreover, the lesion cannot always be differentiated from liposarcoma with imaging methods and definitive diagnosis requires pathologic correlation.
