A CROSS-SECTIONAL ANALYSIS OF DERMOSCOPIC PATTERNS DISTINGUISHING BETWEEN PSORIASIS AND LICHEN PLANUS: A STUDY OF 80 PATIENTS

Penmetcha Lakshmi Chandravathi1, Praneet Awake2, Madhavi Kota3

1Professor and HOD, Department of Dermatology, Venereology and Leprosy, Care Institute of Medical Sciences, Hyderabad, Telangana. 2Post Graduate Student, Department of Dermatology, Venereology and Leprosy, Care Institute of Medical Sciences, Hyderabad, Telangana. 3Post Graduate Student, Department of Dermatology, Venereology and Leprosy, Care Institute of Medical Sciences, Hyderabad, Telangana.

ABSTRACT

BACKGROUND

Dermoscope is non-invasive diagnostic tool, which allows rapid and magnified in-vivo observation of the skin and helps in visualization of morphologic features invisible to naked eye. Dermoscopy is useful in evaluating pigmented lesions, but it can also be used in evaluating the inflammatory skin disorders but little is currently known about their dermoscopic features. Dermoscopy of Psoriasis shows red globules, red lines, red dots, glomeruli-like vessels and light red background. Dermoscopy of Lichen planus shows Wickham's striae, central yellow brown area, grey blue dots, comedo-like opening, corn pearls.

AIMS

To determine and compare dermoscopic patterns of Psoriasis and Lichen Planus and correlate the dermoscopic images with histopathology of Psoriasis and Lichen planus in clinically difficult cases and compare the findings seen in our study with previous studies.

MATERIALS AND METHODS

A cross-sectional comparative study, during course of 2 years, total of 80 cases in which 40 patients each of Psoriasis and Lichen planus were included. Digital dermoscopic images of lesions were obtained with Hanse microscope, after lesions were covered with olive oil. All dermoscopic findings of both psoriasis and lichen planus were observed, captured and data was analysed statistically. In clinically difficult and atypical cases, histopathology was done and correlated with dermoscopy.

STATISTICAL ANALYSIS

For all the statistical analysis SPSS statistical software, version 17.0 for windows (SPSS Inc. Chicago, IL, USA) was used. Chi-square (χ2) test was done for statistical significance. In all instances, a “p” value of 0.05 was considered significant. Charts were prepared with Microsoft Excel 2010 version.

RESULTS

On dermoscopy there is statistical significance at 5% confidence interval of red globules (p=0.001, χ2=37.143), Wickham's striae (p=0.001, χ2=34.286), grey blue dots (p=0.000, χ2=13.067) and glomeruli like vessels (p=0.003, χ2=8.538) in comparison between psoriasis and lichen planus. Dermoscopic findings of psoriasis were predominantly vascular while those of lichen planus were predominantly non-vascular.

CONCLUSION

Clinical use of dermoscopy in inflammatory dermatosis improves diagnostic ability and improves fundamental aspects of daily practice such as improvement of morphologic knowledge for visual tele-dermatology and in addition plays a psychological placebo effect on patients suffering from common inflammatory dermatosis.

KEYWORDS

Dermoscopy, Red Globules, Wickham’s Striae, Psoriasis, Lichen Planus.

INTRODUCTION

Skin surface microscopy was started hundreds of years ago, first in 1663 by Kolhaus. In 1920, Goldman coined the term "Dermoscopy" and showed its use to evaluate pigmented cutaneous lesions.

Psoriasis and lichen planus are common inflammatory skin diseases and their characteristic appearance allows a clinical diagnosis in a high proportion of patients. However, unusual presentations at times do exist and may cause difficulties in the differentiation among these entities. In those cases, histopathology contributes significantly to the accurate diagnosis.

Dermoscope is non-invasive diagnostic tool, which allows rapid and magnified in-vivo observation of the skin and helps in visualization of certain morphologic features invisible to naked eye. It has also been called 'skin surface microscope', 'epiluminence microscope' or 'episcope.' It works on principal of "transillumination" of lesion and studying it with high magnification to visualize subtle features. Thus it forms a link between macroscopic clinical dermatology and microscopic dermatopathology. This "sub-macroscopic" observation of
colours and structures enhances clinical assessment by providing new diagnostic criteria for the differentiation.

Dermoscopic patterns are seen in many common inflammatory dermatoses. Psoriasis vulgaris presents with vascular changes like dotted vessels, red dots and light red background and lichen planus presents with characteristic Wickham’s striae, grey-blue background on dermoscopy. Dermoscopy, besides helping in the diagnosis, can be used to monitor treatment response. Given that Plaque Psoriasis and other inflammatory skin diseases may sometimes be difficult to differentiate clinically, a more detailed determination of specific dermoscopic patterns of inflammatory skin diseases could be a valuable addition for the clinical assessment.

Purpose of this study is to analyse various dermoscopic patterns of psoriasis and lichen planus. With the acceptance of standardized dermoscopic criteria worldwide as diagnostic test would obviate the need for invasive histopathology.

MATERIALS AND METHODS
This is a cross-sectional study, conducted in dermatology clinics of Care institute of Medical Sciences, Banjara Hills, Hyderabad after approval of Institutional Ethics committee. The data was collected from 80 patients, 40 each of psoriasis and lichen planus who attended our OPD according to the inclusion and exclusion criteria, duration of study was 2 years. Inclusion criteria were set as all patients clinically diagnosed as psoriasis or lichen planus, clinically difficult cases or where diagnosis is doubtful are also included, all morphological variants of psoriasis and lichen planus were included, all patients with clinically doubtful findings, but with previous biopsy showing psoriasis and lichen planus. Exclusion criteria includes patients with prior clinical or histopathological evidence other than psoriasis or lichen planus, patients on topical or oral corticosteroids for treatment of psoriasis or lichen planus, one month prior to performing dermoscopy, psoriasis and lichen planus lesions with secondary infection, erythrodermic psoriasis.

The demographic data such as name, age, sex, chief complaints and other history of each case was noted. The diagnosis of psoriasis and lichen planus was made on the basis of standard definitions and clinical features, accepted in literature. Dermoscopic image capturing was performed by a single practitioner to avoid diversification during the procedure. Dermoscopic evaluation was performed by two independent investigators, who were unaware of the histopathological diagnosis. A hand held dermoscope (Hanse microscope-model HV5-CM 500PC), with charge coupled device, imaging sensor of 310 kilo pixels, offering a pixel resolution of 640x480 pixels, with video capability of 30 frames per second and magnification of 20 to 75 factors with automatic gain and exposure control. Digital dermoscopic images of lesions were obtained.

Statistical Analysis
For all the statistical analysis SPSS statistical software, version 17.0 for windows (SPSS Inc. Chicago, IL, USA) was used. Chi-Square ($\chi^2$) test was done for statistical significance. In all instances, a "p" value of 0.05 was considered significant. Charts were prepared with Microsoft Excel 2010 version.

RESULTS AND DISCUSSION
A total of 80 patients were taken into our study, 40 patients each with psoriasis and lichen planus. In psoriasis group, maximum number of patients were male 27(67.5%) and remaining were female 13(32.5%) with mean age group of 37.63 years. In lichen planus group, maximum number of patients were female patients 21(52.5%), and the remaining were male 19(47.5%) with mean age group 34.40 years.

Out of 40 patients of psoriasis, the different morphological variants included were plaque psoriasis 25(62.5%), guttate psoriasis 5(12.5%), hypertrophic psoriasis 5(12.5%), palmar psoriasis 3(7.5%), palmoplantar psoriasis 1(2.5%), and planar psoriasis 1(2.5%). Out of 40 lichen planus cases, hypertrophic LP 12 (40%), eruptive LP 9(22.5%), annular LP 6(15%), linear LP 5(12.5%), follicular LP 3 (7.5%), generalised LP 3 (7.5%) and actinic LP 2 (5%).
The dermoscopic findings in psoriasis cases, maximum showed red globules 27(67.5%) followed by glomeruli like vessels 10(25%). Background colour of light red was seen in 17(42.5%). Grey blue background was noted in 10(40%). Scales in psoriasis cases on dermoscopy were note as silvery white in maximum 35(87.5%) cases, greasy yellow in 3(7.5%), grey blue in 2 (5%) cases. Red globules were observed in 27(67.5%) cases. Next important finding was glomeruli like vessels observed in 10(40%) patients. The only non-vascular finding observed was grey-blue dots, found in 3(7.5%) cases.

The dermoscopic findings in Lichen Planus cases, maximum were Wickham’s striae in 24 (60%) and grey-blue dots in 17(42.5%) cases. Grey blue background colour was noted in 32(45%). Scales on dermoscopy were seen in 10 cases and clinical scales were noted in only 5 cases. Wickham’s striae was the most common non-vascular finding noted in 24 cases of LP. Grey blue dots were seen in 17 cases. Comedo like openings and corn pearl was seen in 1 cases each. One case showed red globules and glomeruli like vessels.

Histopathological examination was done in total of 14(35%) psoriasis cases, out of which 11(27.5%) were dermoscopically consistent with psoriasis and remaining 3(7.5%) were dermoscopically not consistent with psoriasis.

Histopathological examination was done in total of 23(57.5%) lichen planus cases, out of which 15(37.5%) were dermoscopically consistent with LP and 8(20%) cases were dermoscopically not consistent with LP.
The most significant vascular finding associated with psoriasis was red globules 27/40 (67.5%) followed by glomeruli like vessels 10/40 (25%) and red dots 3/40 (7.5%). Red globules on histology correlated with dilated and tortuous capillary loops, glomeruli like vessels with irregular tortuous capillaries and red dots with normal papillary vessels. In a similar study by Vazquez-Lopez, Jose Antonio et al, red globules were seen in all the patients with psoriasis 20/20 (100%). Similarly in another study conducted by Vazquez-Lopez and J. Kreusch et al. 414 consecutive patients with non-tumoral dermatosis were evaluated, of which 40 patients had psoriasis and red globules were seen in all 40 of them (100%).

In study done by Yan Pal, Alex J. Chamberlain et al to distinguish psoriasis from skin carcinomas, red globules were observed in only 32 out of 100 cases (32%). Glomeruli like vessels were seen in 12/100 cases (12%) in a study conducted by Yan Pan, Alex J. Chamberlain et al. However, no other study had documented GLV as significant finding. This difference is likely due to result of variable terminologies used in studies. Red dots were noted in 4/20 (20%) in a study by Vazquez-Lopez, Jose Antonio et al while Vazquez-Lopez and J. Kreusch et al study found no red dots. However interestingly Yan Pal, Alex J. Chamberlain et al study showed red dots in all the patients 100/100 (100%). In our study, light red background was observed to be maximum seen in 17/40 (42.5%) cases of psoriasis while grey-blue background noted in 10/40 (25%). In study by Yan Pan, Alex J. Chamberlain et al light background was observed in 78/100 (78%) and in study by A. Lallas, A. Kyrgidis it was seen in 34/83 (41%) cases of psoriasis. In our study, grey-blue background was observed in hypertrophic psoriasis cases. Grey-blue background was not observed in previous studies as they have not included various morphological variants into their studies.

In our study, scales were noted in all psoriasis cases. Silvery white scales was most commonly seen in 35/40 (87.5%) psoriasis cases, greasy yellow scales in 3/40 (7.5%). In study by A. Lallas, A. Kyrgidis et al. white scales were noted in 58/83 (70%) psoriasis cases. The most significant dermoscopic finding of lichen planus observed in our study was Wickham’s striae noted in 23/25 (92%) and in study by Y. Park, J. Park it was seen in 1/2 (50%) cases of lichen planus. In a similar study by Vazquez-Lopez, Jose Antonio et al, Wickham’s striae was observed in 24/25 (96%) lichen planus cases. The results of Wickham’s striae in our study were slightly less compared to their study because we have taken only clinically consistent cases but in their study all biopsy proven cases were included. Wickham’s striae on histology correlates with the increased granular layer. The next common non-vascular finding in our study in lichen planus cases was grey-blue dots seen in 17/40 (42.5%). In study by Vazquez-Lopez et al. it was seen in 2/25 (20%) cases. Grey-blue dots correlates on histology with melanophages in dermis.

As per statistical analysis, there is statistical significance at 5% confidence interval (p=0.001, \( \chi^2=37.143 \)) of red globules in comparison of psoriasis and lichen planus. There is also a statistical significance at 5% confidence level (p=0.001, \( \chi^2=34.286 \)) of Wickham’s striae, grey blue dots (p=0.003, \( \chi^2=13.067 \)) and glomeruli like vessels (p=0.034, \( \chi^2=8.538 \)) in comparison between psoriasis and lichen planus.

**DISCUSSION**

Our study suggests significant differences in the dermoscopic features of common inflammatory dermatosis psoriasis and lichen planus. In our study while comparing the dermoscopic findings of both psoriasis and lichen planus, vascular features were observed to be significantly high in psoriasis and non-vascular features were significantly high in lichen planus.
The next finding in lichen planus cases was yellow blue dots in 6/40 (16%) 925 in our study, which was comparable with the study conducted by Vázquez-Lopez et al 5/25(20%). Yellow-blue dots on histology correlates with vascular changes in basal cells and spongiosis. Other non-vascular findings seen our study were comedo like openings in 1/40(2.5%), corn pearl in 1/40(2.5%), milium like cysts were not seen in our study. In study by Vázquez-Lopez et al.3,7 the findings were comedo like openings in 4/25 (16%), corn pearl in 3/25 (12%) and milium cyst in 1/25 (4%).

Vascular findings were not significant in lichen planus patients. In our study histopathological correlation was done prospectively to compare and confirm the dermoscopic findings, thereby having advantage of obviating the need for invasive biopsy in patients. While in previous studies all biopsy proven cases were included. The number of patients included in our study though slightly more than previous studies is still found to be small, especially while comparing rare findings.

CONCLUSION
In our study, almost all cases of psoriasis showed predominantly vascular findings. Among vascular findings we found red globules to be the most common finding. It is consistent with other previous studies done by Vázquez-Lopez et al.3,4,7 In lichen planus, non-vascular findings, mainly Wihlam’s striae was the most common finding seen. In our study, dermoscopy enhanced the demonstration of Wihlam’s striae which were not visible with the naked eye.7,9 After observing different dermoscopic findings in psoriasis and lichen planus we are able to diagnose both the diseases dermoscopically with consistent findings without the need for invasive skin biopsy. Our observations clearly showed that simultaneous evaluation of both vascular and non-vascular findings improves surface microscopy of inflammatory dermatosis.3,9 In conclusion, dermoscopy is a valuable tool for improving the accuracy of differentiation of non-pigmented scaly lesions. It provides a quick, simple and non-invasive aid.

The major benefit from improved dermoscopic differentiation of these common scaly lesions is a reduction in need for a skin biopsy. In addition, dermoscopy also helps in monitoring the response to therapy. Finally we must take into account that clinical use of dermoscopy in inflammatory dermatosis not only improves the diagnostic ability but also improves other fundamental aspects of daily practice and addition of new easily recognizable images for visual tele-dermatology. It has a positive psychological placebo effect on patients suffering from common dermatosis being examined by means of dermoscopy instead of naked eye cannot be neglected. The definitions of dermoscopic findings of inflammatory scaly diseases should be standardized all over the world.

LIMITATIONS
Biopsy could not be done in all the cases due to lack of consent from the patients. In spite of dividing psoriasis and lichen planus into different morphological variants we could not correlate any specific dermoscopic findings with the morphological variants due to small sample size. These limitations should be assessed in the future studies.
