ABSTRACT

BACKGROUND
Incontinentia pigmenti is a rare, X-linked dominant multisystem genodermatosis that presents at or soon after birth with characteristic cutaneous signs. The main features occur in the skin where a blistering rash occurs in the newborn period, followed by the blisters becoming raised like warts. After the skin, the central nervous system is the next most affected system.

CASE REPORT
We report a newborn female baby who was born with vesicular eruptions, initially thought to have congenital herpes simplex virus infection.

CONCLUSION
This case report emphasises that Incontinentia pigmenti should be included in the differential diagnosis of cutaneous blistering lesions and central nervous system involvement in neonates.

KEYWORDS
Incontinentia Pigmenti, Herpes Simplex Virus, Newborn.

BACKGROUND
Incontinentia pigmenti (IP), also known as Bloch-Sulzberger syndrome, is a rare, X-linked, dominant condition characterised by developmental abnormalities of the skin, hair, teeth, and central nervous system (CNS). After the skin, the CNS is the next most affected system.¹ The cause of IP has recently been traced to a defective gene on the X chromosome called NEMO/IKK-gamma, which is located on chromosome Xq28. The NEMO/IKK-gamma gene produces a protein that is essential for cells in the signalling pathways of apoptosis and inflammatory responses.²

The main features of IP are found in the skin where a blistering rash occurs in the newborn period. In this report, we describe a newborn that had vesicular eruptions and seizures and was initially thought to have congenital herpes simplex virus (HSV) infection.
A female newborn was referred to our neonatal unit because of vesicular skin lesions on the upper and lower extremities. She was born at full term to a 25-year-old primigravida mother by caesarean section in Krishna Hospital. Maternal history was not significant. Prenatal and natal history was unremarkable.

On admission to our neonatal unit, physical examination revealed a well-appearing, afebrile infant, with erythematous vesicles on a red base arranged in linear groups on the upper and lower limbs. Septic screening was found to be negative; local therapy with antibiotics was initiated. On the 5th day, baby developed a seizure, which was characterised by a staring gaze and motor manifestations such as diffuse extension with hypertonia of the upper limbs. These episodes occurred two times over 1 hr, and each lasted approximately 30-40 sec.

Results of laboratory studies included a haemoglobin concentration of 16.9 g/L, haematocrit value of 50.5%, white blood cell count of 20,880/mM 3 with 81% neutrophils, 19% lymphocytes, 2% band forms, and the platelet count was 2.85 lakhs/mm 3 . Serum biochemical values, including C-reactive protein, electrolytes were in the normal range.

Magnetic resonance imaging of the brain showed multiple areas with cytotoxic oedema in the bilateral frontal, occipital, temporal region (L > R), midbrain, pons, genu & splenium of corpus callosum. A lumbar puncture revealed 0.5 mL of clear, colourless fluid without any cells, Glucose-80 mg/dL, and Protein-79 mg/dL. No bacterial growth seen in the blood and cerebrospinal fluid culture.

HSV-1 immunoglobulin (Ig) G was positive, and HSV-1 IgM, HSV-2 IgG, and IgM were negative in the serum. The polymerase chain reaction assays for the HSV-1 and HSV-2 deoxyribonucleic acid in the serum and cerebrospinal fluid were not done. The infant was empirically given intravenous acyclovir for suspected congenital herpes simplex infection and phenobarbital for the management of seizures. No other abnormal findings were noted.

Culture of vesicle fluid was negative for bacteria. The ophthalmologic examination was normal. Electroencephalography shows normal study. Magnetic resonance imaging (MRI) of the brain demonstrated - in figures below.

As skin biopsy specimen showed eosinophilic spongiosis and dyskeratotic epithelial cells adjacent to spongiotic microvesicles, it was realised that this is consistent with a diagnosis of IP, and the treatment with acyclovir and antibiotics was discontinued.
The gynaecologic, dermatologic, and ophthalmologic examinations of the mother were found to be normal, and family history in conjunction with the neurologic, ophthalmologic, and dermatologic findings was unremarkable.

**DISCUSSION**

Incontinentia pigmenti is X-linked disorder affecting Skin, Hair, Teeth and Central Nervous System. In most patients, the syndrome occurs sporadically. Germline mutations inherited from the father have been reported in more than 80% of cases of sporadic disease.[2]

The skin changes are the most characteristic feature in IP which occurs in 4 stages. The first stage which may be present at birth consists of redness/inflammation (Erythema) of the skin, blisters and boils. It may be seen in 90% of the patients. It may last for few weeks to few months. It may reduce in intensity but later reappear in some cases when there is illness with fever.

The second stage, may overlap with the first, characterised by blisters which develop a raised verrucous (Wart-like) surface and is seen on the extremities. There can be thick crusts or scabs with healing and areas of darkened skin. This stage may last for several months.

The third is the hyperpigmented stage that appears usually between 6-12 months of life. The skin is darkened in a swirled pattern giving a “marble cake” appearance. These hyperpigmented areas do not necessarily coincide with the sites where the stage I and II rashes occurred. The heavy pigmentation tends to fade over time and, in few cases, the pigmented areas thin and widen, leaving streaky diminished colour of the skin (Hypopigmentation).

In the fourth stage, known as the “atrophic” (Scarred) stage, scarring is often present before the hyperpigmentation fades and these are seen in adolescents and adults as pale, hairless patches or streaks. Once the affected individuals reach the late teens and adulthood, the skin changes may fade and may not be visible to the casual observer.

Apart from the clinical findings of skin lesion, the most commonly involved other sites are CNS and visual systems which should be investigated. The CNS is involved in 10-40% of patients in the form of microcephaly, strokes, seizures, mental retardation, spasticity, and ataxia. Of these, seizure is the most common complication and usually develops within the first few weeks of life. Cerebral microangiopathy and haemorrhagic infarcts cause some of the neurologic morbidity.

MRI abnormalities include cortical malformations such as heterotopia, hemimegalencephaly, focal cortical dysplasia, callosal dysgenesis as well as cortical atrophy, and periventricular/white matter lesions.[3] Ocular changes are seen in about one third of patients with IP. Ophthalmologic findings can include retinal pigmentary changes with mottled hypopigmentation, abnormal peripheral retinal vessels with areas of nonperfusion (these two findings are nearly pathognomonic), retinal detachment, cataracts, microphthalmia, optic atrophy, or foveal hypoplasia. Prognosis is good if ocular and CNS abnormalities do not appear by the age of 1 year.[4]

Vesiculopustular disorders of neonates are common; HSV infection, herpes zoster, congenital syphilis, neonatal acne, staphylococcal infections, bullous impetigo, epidermolysis bullosa simplex, Letterer-Siwe disease, transient purpuric melanosis, neonatal dermatitis herpetiformis, and IP all have vesiculopustular cutaneous manifestations.[3] In newborns, many examples of erroneous diagnoses of vesiculopustular disorders, made as a result of suspicious findings, can be found in the literature, Herpes simplex being the most common one.[6,7,8] Neontal HSV infection can show up any time from soon after birth up to and beyond the neonatal period. Seventy-five to 90% of infants with neonatal HSV are born to women with no history or physical findings suggestive of genital herpes. Exposure to the virus occurs during passage through an infected birth canal, but 5% infants acquire the infection in utero. Disease can be localised to the skin, eye, and mouth, which without treatment, 70% of cases progress to a disseminated form involving the CNS or disseminated infection involving multiple organs. On pathology, HSV cause a haemorrhagic and necrotising meningencephalitis.[9]

**CONCLUSION**

Owing to high mortality and morbidity of neonatal HSV infection, it is imperative that we initiate an early acyclovir therapy in neonatal vesicular eruptions, until a detailed clinical and laboratory evaluation can be done. In this case, the cutaneous lesions and CNS manifestations led us to a diagnosis of HSV infection. However, it was the MRI findings and the skin biopsy results that finally clinched the diagnosis of Incontinentia pigmenti. In conclusion, this case report emphasises that IP is a potential masquerader of HSV infection and should be included in the differential diagnosis of cutaneous blistering lesions and CNS involvement in neonates. Lastly, this case emphasises the importance of skin biopsies in vesicular lesions with CNS involvement.
