ABSTRACT

BACKGROUND
Appendicitis is a disease of young adults with 40% of cases occurring in patients between the ages of 10 and 29 years. Appendectomy is the most commonly performed urgent abdominal surgery. This study aims at revealing hyperbilirubinaemia as a laboratory marker for diagnosing the severity of acute appendicitis based on correlation between hyperbilirubinaemia and intra-operative findings in patients undergoing emergency appendectomy for acute appendicitis.

MATERIALS AND METHODS
This descriptive study reviewed the correlation of hyperbilirubinaemia and acute appendicitis and its complications among the 237 patients who had undergone open or laparoscopic appendectomy (after excluding patients with other causes of hyperbilirubinaemia) in our institution from January 2015 to July 2017. A retrospective chart review of medical records, lab investigations and intraoperative findings were recorded and the data was analysed.

RESULTS
Among 237 patients who had undergone emergency open or laparoscopic appendectomy during this interval, hyperbilirubinaemia was found in 89 patients (37.55%). Among these 72 patients (80.90%) had perforated or gangrenous appendix, whereas appendix was found to be inflamed in 17 patients (19.10%). Normal levels of serum bilirubin was found in 148 patients (62.44%), out of which 32 patients (21.62%) had perforated appendix and remaining 116 patients (78.38%) had inflamed appendix.

CONCLUSION
In our study hyperbilirubinaemia was found in 12.78% of patients with acute appendicitis without any complication, whereas hyperbilirubinaemia was seen in 69.23% of patients with acute appendicitis with perforation/gangrene. Thus, serum bilirubin can be used as an adjunct laboratory tool for diagnosing the severity of acute appendicitis.

KEYWORDS
Hyperbilirubinaemia, Acute Appendicitis.

BACKGROUND
Appendicitis is a disease of young adults with 40% of cases occurring in patients between the ages of 10 to 29 years.1 Appendectomy is the most commonly performed urgent abdominal surgery.2 Although, most patients with acute appendicitis can be easily diagnosed, in some cases signs and symptoms are variable and a firm diagnosis can be difficult. Delay in surgery in these cases due to any reason- delayed presentation or mistaken judgement leads to dreaded complications like gangrenous changes and perforation.

The incidence of perforated appendix in adults has been reported from 13% - 37%.3 A timelier and more accurate diagnosis has been attempted by the use of additional laboratory tests,4,9 scoring systems,10-13 sonography,14,15 computed tomography,16,17 but none of these methods stand alone as they all come in support of and are secondary to a primary clinical diagnosis. Increasing use of CT scanning in acute appendicitis increases the cost of care, stay time in the emergency department and delays the time for surgery.18

The association between elevated serum bilirubin levels and infectious diseases has been noted in certain studies. Studies conducted by Estrada et al.19 and others20,21 demonstrate a nearly three-fold risk of perforated appendicitis in patients with total serum bilirubin levels more than 1 mg/dL.

Physical examinations and laboratory tests are still acknowledged to be of utmost importance in diagnosing acute appendicitis.22 We tried to find key laboratory tests that would allow us to anticipate the severity of acute appendicitis. This
study is done to evaluate the association between hyperbilirubinaemia in cases of acute appendicitis and its complications. The establishment of a possible role of hyperbilirubinaemia as a predictor of perforated/gangrenous appendicitis has been stressed, so that serum bilirubin levels upon admission can be used in conjunction with other diagnostic tests to help determine the severity of acute appendicitis and aid in proper clinical management.

Objectives
To study the co-relation between serum total bilirubin and acute appendicitis, particularly perforated/gangrenous appendicitis and to know whether hyperbilirubinaemia can be used as a marker for diagnosing the severity of acute appendicitis, particularly appendicular perforation or gangrene in preoperative period.

MATERIALS AND METHODS

Study Design
This is a descriptive study based on data collected from the case sheets of patients who had undergone emergency appendectomy for acute appendicitis during January 2015 to July 2017 in the Department of Surgery, Dr. RPGMC Tanda (HP) after observing inclusion and exclusion criteria.

Inclusion Criteria
All patients irrespective of age who had undergone emergency open or laparoscopic appendectomy for acute appendicitis based on clinical examination during this period.

Exclusion Criteria
All patients with documented history of jaundice/liver disease, chronic alcoholism, haemolytic disease, biliary tract disease, HBsAg positive, hepatobiliary tract malignancy were excluded from the study.

The patients were divided into two groups. Group ‘A’ includes those patients with acute appendicitis in whom intra-operatively appendix was found to be inflamed and turgid but not perforated and Group ‘B’ of patients with intra-operatively perforated or gangrenous appendicitis.

The results were analysed by chi-square test using Epi Info Software version 7.1.3.0.

RESULTS
A total of 239 emergency appendectomies were performed during this interval in our institution. Out of these, one patient of acute appendicitis with cholelithiasis (USG finding) and the other one, acute appendicitis with ileal perforation (intra-op finding) were excluded from this study. Rest 237 patients, Males 144 (60.76%), Females 93 (39.24%) who had undergone emergency appendectomy with a clinical diagnosis of acute appendicitis or appendiceal perforation were included in the study.

1. Out of 237 emergency appendectomies done during this interval, 133 patients (56.12%) had inflamed and turgid appendix (non-perforated/gangrenous), i.e. Group ‘A’ and 104 patients (43.88%) had perforated appendix intra-operatively, i.e. Group ‘B’ (Table 1).

2. Mean total serum bilirubin of 237 patients (Group ‘A’ + Group ‘B’) was 1.04 mg/dL (with an SD of 0.8), which was above the normal range (≤ 1.0 mg/dL). In Group ‘A’ out of total of 133 patients, the mean of total serum bilirubin was 0.69 mg/dL (with an SD of 0.58), which was below the normal range (≤ 1.0 mg/dL). In Group ‘B’ the mean of total serum bilirubin was 1.48 mg/dL (with an SD of 0.82), which was above the normal range (≤ 1.0 mg/dL).

3. Out of total of 237 patients (Group ‘A’ + Group ‘B’) who had undergone emergency appendectomy, 148 patients (62.44%) had normal bilirubin levels (≤ 1.0 mg/dL), while 89 patients (37.56%) had raised bilirubin levels (> 1.0 mg/dL). In Group ‘A’ out of total of 133 patients, 116 (87.22%) patients had normal bilirubin (≤ 1.0 mg/dL) levels, whereas 17 (12.78%) patients had raised bilirubin levels (> 1.0 mg/dL). In Group ‘B’ out of total of 104 patients, 32 (30.77%) patients had normal bilirubin levels (≤ 1.0 mg/dL), whereas 72 (69.23%) patients had raised bilirubin levels (> 1.0 mg/dL).

4. Of 133 patients in Group ‘A’, i.e. acute appendicitis without any perforation/gangrene, only 17 patients (12.78%) had raised serum bilirubin levels (> 1.0 mg/dL) preoperatively, while the remaining 116 patients (87.22%) had normal serum bilirubin levels (≤ 1.0 mg/dL). Out of 104 patients in Group ‘B’ in whom intraoperatively appendix was found to be perforated/gangrenous, 72 patients (69.23%) had raised serum bilirubin levels (> 1.0 mg/dL) preoperatively, while the remaining 32 patients (30.77%) had normal serum bilirubin levels (≤ 1.0 mg/dL).

These results were analysed using chi-square tests Epi Info version 7.1.3.0 with a “p” value < 0.001, which is highly significant (Table 3).

**DISCUSSION**

The incidence of acute appendicitis varies from 7 to 22 per 10,000 population. Appendicitis is most frequently seen in young patients in their 2nd to 4th decade of life with a mean age of 31.3 years and a median age of 22 years. Obstruction to the lumen is believed to be the major cause of acute appendicitis. Fecaliths are the usual cause of obstruction and less common causes are hypertrophy of lymphoid tissue, tumours, intestinal parasites, non-perforated acute appendicitis can be cured by appendectomy without any long recovery period, whereas delay in diagnosis and surgery in these patients can lead to dreaded complication like perforation and gangrene.

In our study, out of 237 patients increased serum bilirubin levels (>1.0 mg/dL) were observed in 89 patients (37.55%), while remaining 148 patients (62.45%) had normal levels (≤1.0 mg/dL). Out of 89 patients with hyperbilirubinaemia, 72 patients (80.9%) had perforated appendix and remaining 12 patients (19.1%) had uncomplicated appendicitis.

When the results were analysed taking into consideration the pre-operative serum bilirubin levels in either group ‘p’ value of total serum bilirubin was calculated to be <0.001, which was highly significant. Since these tests were done prior to the surgery, it is unlikely that liver injury because of anaesthetic drugs was the cause of liver injury. The most likely cause of rise in serum total bilirubin is circulating endotoxinaemia.

A study conducted by Utiλ et al demonstrated in rats also shows the similar results. The study conducted by Sisson et al demonstrates that gangrenous or perforated appendicitis is associated with progressive bacterial invasion into the muscularis propria of appendix, which is facilitated by bacterial cytokotoxins. Study conducted by Estrada et al had found significantly higher peritoneal culture in patients with gangrenous/perforated appendicitis.

Studies conducted by Estrada et al and others demonstrated a nearly three-fold risk of perforated appendicitis in patients with total serum bilirubin levels more than 1 mg/dL.

In the study conducted by Dr. A. Q. Khan et al, Sensitivity and Specificity of bilirubin in predicting appendicular perforation 88% and 80% respectively; similarly, positive predictive value and negative predictive value of bilirubin in predicting appendicular perforation 81.48% and 86.96% respectively. In the study done by Emmanuel et al found out specificity of hyperbilirubinaemia for appendicular perforation was found to be 70%.

Several mechanisms have been described explaining serum bilirubin elevations in systemic infections. The haemolysis produced by certain bacteria including E. coli, produces an increase in indirect and total bilirubin. Also, some endotoxins released in the peripheral blood stream are responsible for impeding the liver’s mechanisms for bilirubin uptake and canalicular excretion. Endotoxin produce cholestasis by damaging biliary salt transport through cytokine-mediated mechanisms. Elevated serum bilirubin levels in acute appendicitis can either appear as a result of bacteraemia or endotoxinaemia, both possible in the catarrhal and phlegmonous forms as well as in the gangrenous or perforated ones. Before 1950, about 0.4% cases of acute appendicitis were complicated with superior mesenteric vein thrombophlebitis and now this complication has become very rare in the present era due to antibiotics and early surgical intervention.

**CONCLUSION**

Elevation in serum bilirubin levels can be used as a criterion to diagnose acute appendicitis with perforation/gangrene. Measurement of total serum bilirubin levels is simple, cheap and available in every laboratory and can be added to the routine investigation list of clinically suspected cases of acute appendicitis for early identification of its complications. In our study, out of 237 patients with acute appendicitis, hyperbilirubinaemia was found in 69.23% of patients with perforated/gangrenous appendicitis against 12.78% of patients with acute appendicitis without any complication.
