PRESENTATION OF CASE

A 78 yrs., old female patient presented with history of recurrent right lower abdominal pain and burning micturition since 3 months. She had an episode of foul-smelling vaginal discharge 10 days back. She had undergone abdominal hysterectomy and bilateral salpingo-oophorectomy for adenomyosis 26 years back and vaginal vault repair for cystocele 4 years back. She is known hypertensive and is on antihypertensive medication for past 10 years. A full review of systems was otherwise negative, including the absence of haematochezia, melena, nausea, vomiting, appetite change and weight loss. She had an unremarkable abdominal examination, including the absence of tenderness to palpation, palpable masses, and peritoneal signs. Laboratory investigation revealed ESR 80 mm/hr, with Hb 9.9 gm/dl and normal total count. URE done was normal.

Colonoscopy revealed diminutive polyps in sigmoid colon from which biopsy was taken. No mass lesion/ulceration were observed. Ascending and descending colon were found to be normal. CT Scan (both plane and contrast) revealed 20 mm dilated inflamed appendix with minimal vaginal fluid and enhancing wall thickening of vaginal vault with apparent fistulous connection between appendicular tip and vaginal vault. MRI confirmed the above findings.

CLINICAL DIAGNOSIS

Acute appendicitis.

DIFFERENTIAL DIAGNOSIS

- Pelvic inflammatory disease
- Pelvic abscess

DISCUSSION OF MANAGEMENT

She underwent laparoscopy. Intraoperatively appendix base was friable; tip was perforated with a fistulous tract with the vaginal vault. Appendicectomy was done and fistulous tract was excised, and vaginal vault opening was closed. There was no intraperitoneal deposits or lymph nodes. Since gross and microscopic pathological examination revealed mucinous adenocarcinoma of appendix, she underwent laparotomy. Intraoperatively there were serosal nodules over the cecum and multiple mesenteric lymph nodes. Hemicolecotomy was done with ileotransverse side to side anastomosis.
Gross and microscopic pathological examination revealed mucinous adenocarcinoma of appendix. Further pathological examination of hemicolectomy specimen revealed mucinous adenocarcinoma of appendiceal stump with few signet ring cells. Focal tumour deposits in the caecal subserosa with mesenteric deposits. Fistulous tract also showed malignant cells. 1/11 lymph node was found to have metastasis.

**PATHOLOGICAL DISCUSSION**

Primary adenocarcinoma of the appendix is rare condition. It accounts for 0.12 cases per 1000000 patients per annum, 0.05%-0.2% of all appendectomies, about 0.2% of all gastrointestinal neoplasms, and only 6% of appendiceal cancers.[1,3] The typical patient is older, and duration of symptom is usually longer.[1] There are four major histological subtypes of appendiceal adenocarcinoma: cystic, colonic, carcinoid, and adeno-carcinoid. Carcinoids are the most common, comprising nearly 90% of all primary appendiceal tumours while mucinous cystadenocarcinoma is the second most common type.[2] Appendiceal adenocarcinoma is further divided into colonic, mucinous (MAA), goblet cell, and signet ring cell types.[3,4] Primary signet ring cell carcinoma of the appendix is an exceedingly rare entity, comprising only 4% of all appendiceal neoplasms.

MAA usually presents with nonspecific findings. It frequently presents with acute abdominal pain resembling acute appendicitis; sometimes presents as an abdominal mass detected by palpation or abdominal imaging rarely presents with nausea, vomiting, ascites, or involuntary weight loss.[5,6,7] Due to its nonspecific presentation malignancy of the appendix are never diagnosed preoperatively and seldom intraoperatively, the diagnosis being usually made at histopathological examination of the surgical specimen or as an incidental finding during exploration for another disease.[6] MAA usually a non-invasive, low grade malignancy with less chance of distant metastasis. However, the signet ring type is high grade with chance of metastasis. Unfortunately, our case has few signet ring cells which is a rare entity.[8]

MAA frequently causes appendiceal perforation attributed to the mucinous gel obstructing the lumen and the narrow appendiceal lumen.[9,10] Details regarding the therapy for MAA is sparse. Surgical management is the mainstay. Right hemicolectomy is done when appendicectomy specimen reveals adenocarcinoma.[11]

CT Abdomen and pelvis and colonoscopy are essential before doing hemicolectomy to rule out metachronous/synchronous lesions. Presence of peritoneal spread requires surgical debulking by primary tumor excision, right hemicolectomy, lymph node dissection, omentectomy, peritoneotomy, and removal of malignant ascites. Patients with intraperitoneal lymphadenopathy or PMP benefit from adjuvant intraperitoneal hyperthermic chemotherapy. The drugs used intraoperatively for hyperthermic chemotherapy are mitomycin (Mutamycin), cisplatin, and doxorubicin or oxaliplatin (Eloxatin). Most patients who receive heated
intraoperative intraperitoneal chemotherapy are also given early postoperative intraperitoneal fluorouracil (5-FU) or paclitaxel(12). There are studies where patient benefitted from 12 cycles of oxaliplatin, 5-fluorouracil, and leucovorin (FOLFOX-4).(12) Frequent colonoscopy is required after surgery since incidence of metachronous cancer is 17%.(2)

**FINAL DIAGNOSIS**

Mucinous adenocarcinoma of appendix with appendicovaginal fistula.
