ABSTRACT: We report a case of post operative repeated wound infection due to Mycobacterium Tuberculosis. A 25 yr old woman presented to us with watery discharge from Caesarean section wound, done elsewhere 3 months ago. Discharge from the wound showed Acid fast bacilli on Ziehl Neelsen stain, and Histopathology report confirmed tubercular infection. Patient was treated with standard anti tubercular drugs, and is responding well to treatment. A high degree of suspicion is required for exact identification of unusual pathogens in cases of recurrent postoperative wound infection.

KEY WORDS: Wound infection, Caesarean section, Tuberculosis

INTRODUCTION: Post operative wound infection is common in routine surgeries. Etiology of infections may vary from patient to patient, hospital to hospital, depending upon the patient's condition and sterility. Most often the infection is due to anaemia, malnutrition, immunodeficiency, diabetes, obesity and during emergency surgeries. In obstetrics the added causes are prolonged labour, prolonged rupture of membrane etc., (1). However wound infections due to Mycobacterium tuberculosis is a very rare entity (2, 3). Here is the patient who presented to us with a rare complication of repeated wound infection following LSCS, due to Mycobacterium Tuberculosis.

CASE REPORT: A 25 year old primipara presented to us in the Obstetrics and Gynecology Department of ASRAM Medical college, 3 months after a LSCS done elsewhere, with history of recurrent watery discharge from postoperative wound site (Figure 1). There was no history of fever or tenderness over the wound or palpable regional lymph nodes. On exploring the wound, it easily gave way, but the margins of the wound appeared healthy. Daily dressing was done and appropriate antibiotics were started simultaneously. Secondary suturing was done after 7 days of daily dressing and patient was discharged well after 10 days. Ten days later patient presented again to the OPD with similar complaints of wound discharge. At this admission, wound was explored and pus discharge was sent for Ziehl Neelsen stain for Acid fast bacilli and tissue from the margins of the wound was sent for histopathological examination. Ziehl Neelsen stain showed positive for AFB
CASE REPORT

and Histopathology report revealed areas of cell necrosis, giant cells and diffuse collection of lymphocytes and granulation tissue which is suggestive of tuberculosis (Figure 2). Blood investigation and Chest X ray revealed no abnormality. Patient was treated with standard antitubercular drugs.

DISCUSSION: Postoperative recurrent wound infection due to Mycobacterium Tuberculosis is a rare, recognised complication of surgery. Globalisation of tuberculosis with high prevalence is reported in developing countries like Bangladesh, Pakistan and India (4,5). We report a case of post operative repeated wound infection caused by Mycobacterium Tuberculosis. The patient neither had the clinical symptoms of tuberculosis nor a close family member suffered from the disease. So the diagnosis and initiation of treatment was delayed until confirmation of the disease by histopathology. The patient was started on Anti-tubercular treatment (ATT) and is responding to the treatment satisfactorily. Therefore high degree of suspicion is required for exact identification of pathogen, especially in cases of recurrent postoperative wound infections.

ACKNOWLEDGEMENT: First of all we would like to thank our innocent ailing patient who silently contributed to our academic activities and management of unusual complications. We like to thank our Head of the department for his help and valuable suggestion and guidance. We would like to thank pathology and microbiology departments for helping us with the diagnosis.
