ABSTRACT

BACKGROUND
Knowledge of the recovery profile from a spinal anaesthetic is helpful in predicting time to meeting discharge criteria from an ambulatory surgery center. Upper abdominal surgery takes 2 to 3 hours. Which was previously considered inappropriate for the ambulatory setting, surgery is now being performed on outpatients under spinal anaesthesia. Therefore, it is important for anaesthesiologists to know the recovery profile of Bupivacaine and Bupivacaine with Fentanyl. There is always need of search of such a drug combination which reduces the hospital stay of patient with minimal side effects. This study explores the use of long acting local anaesthetic Bupivacaine and Bupivacaine with Fentanyl for upper abdominal surgery.

METHODS
120 patients undergoing upper abdominal surgery were enrolled in a double-blinded clinical trial study. Patients were randomly allocated into two groups. Group A received 17.5 mg(3.5 ml) of Bupivacaine and Group B received Bupivacaine 15 mg and 25 µg of Fentanyl (3.5 ml) as intrathecal drug for spinal anaesthesia. Sensory and motor blockade scores, postoperative pain scores and need of analgesic injection 6 and 12 hours after surgery, postoperative voiding time, and the incidence of hypotension, bradycardia, respiratory depression, and nausea and vomiting were recorded. Ambulation time and discharge from hospital were also recorded.

RESULTS
Complete analgesia (time from injection to first report of pain) time was more in group BF i.e., 146±8.5 min, and voiding time was also more in group BF i.e., 10.3 hours (618± 34 min), and 3% patients developed pruritus postoperatively. The average time of discharge was same in both groups but need of analgesic was less in group B. Patients in group BF were more comfortable during post-operative period except 2 patients who develops pruritus.

CONCLUSIONS
Bupivacaine with intrathecal fentanyl 25 µg produces a satisfactory surgical block, significantly decreases the need of analgesic supplementation, but increases the voiding time. early ambulation occurs in this group. There are no side effect of intrathecal fentanyl. It is very good for patients. Thus, overall effect of Bupivacaine and Fentanyl is superior to Bupivacaine alone, apart from positive effects of fentanyl, it decreases the requirement of bupivacaine and has no side effects.

KEYWORDS
Bupivacaine, Fentanyl, Ambulatory Surgery

**METHODS**

This study was conducted at A. K. Tibbiya College hospital over the period of one year. After receiving approval from institutional ethical committee, and a written consent were taken from all patients. 60 patients of ASA 1 and 2 between age of 18–65 years and weight of 45 to 90 kg were scheduled for upper abdominal surgery, underwent spinal anaesthesia. Exclusion criteria include, patient having cardiac problem, uncontrollled diabetes and hypertension and use of alcohol addiction and sedative drugs. PAC was done and Tab clonazepam (0.25 mg) was given to all patients, night before surgery. On arrival of patient into operating room ECG, SpO2, non-invasive BP were monitored, all patients were preloaded with 5-10 ml/kg of ringer lactate before spinal anaesthesia. Under all aseptic precautions, after infiltration of local anaesthesia, Lumber puncture were performed in sitting position through midline approach. Patient were randomly divided into two groups. Group A received 17.5 mg (3.5 ml) of Bupivacaine. Group BF received 15 mg of Bupivacaine and 25 µg of Fentanyl (3.5 ml) by volume. After spinal anaesthesia patient were immediately placed in supine position with head end tilted by 15 degrees and 2 L/min of oxygen was given through Hudson mask.

The blinded observer recorded the time of spinal anaesthesia and time of onset of motor block. Sensory block was assessed by using analgesia to pin prick by blunt tip needle. The investigator moved the safety pin from caudal to cephalad. Motor block was assessed by using modified Bromage scale which are mentioned as under. The time to reach T5 dermatome sensory block were recorded. All duration of sensory and motor block were calculated, considering the time of injection as time zero. Pulse and non-invasive blood pressure were measured every 5 minutes for first 30, minute and there after every 10 minutes. If the blood pressure fell below 90 mmHg, injection Mephentermine was given, bradycardia defined as heart rate below <60 beat / minute were treated with Atropine. Incidence of nausea, vomiting, shivering, pruritus and sedation given were recorded. SpO2 was monitored continuously in the operating room. After completion of surgery patient were shifted to ward and nurses on duty were instructed to observe and note the time of analgesic requirement, nausea, vomiting, pruritus, spontaneous voiding and leg movements.

**Modified Bromage Scale**

Grade 0 = no block, full straight leg raise possible.
Grade 1 = inability to elevate extended leg (Able to flex knee).
Grade 2 = inability to flex knee (Able to move foot only).
Grade 3= inability to flex ankle.
Grade 4 = Complete motor paralysis.

**Statistical Analysis**

In this study, 120 patient receiving spinal anaesthesia using hyperbaric Bupivacaine (17 mg), and Bupivacaine with fentanyl (15 mg + 25 µg) underwent upper abdominal sugary. Demographic data were analysed using student t - test. The incidence of hypotension, bradycardia, analgesic requirement, nausea, vomiting, were compared using Chi – square test. Student t –test was used to compare the

**RESULTS**

The two groups were comparable with respect to ASA status, age, weight, height, and duration of surgery as shown in Table I.

**DISCUSSION**

Bupivacaine, an amide type of local anaesthetic, has high potency, slow onset (5–8 minutes) and long duration of variables, eg, time of urination, and ambulation. And hospital stay time.
action (1.5–2 hours). Administration of fentanyl intrathecally is an established method for Intraoperative anaesthesia and to supplement post-operative analgesia. Fentanyl acts on opioid receptors or other nonspecific binding sites in the spinal cord. Result of this study showed that Fentanyl 25 μg prolongs the duration of Bupivacaine induced sensory blockade. This suggests a potential synergism between Fentanyl and Bupivacaine, as reported by Wang et al. Advantage of using intrathecal fentanyl is its extremely rapid onset of action. Analgesia has been reported to occur within 5-10 minute. In our study this time is 6±1.1 minute. Ben-David et al showed that fentanyl added to bupivacaine could reduce the dose of local anaesthetic to 5 mg and still provide sufficient analgesia for arthroscopy. We did not find any studies in the literature in which small doses of plain hyperbaric bupivacaine were used for outpatient herniorrhaphy, and there is only one study in combination with fentanyl. In that investigation, fentanyl was given in a dose of 25 μg as an adjuvant to 9—11.25 mg of bupivacaine. This combination produced good analgesia, but we need motor block up to T5 so by giving small dose as mentioned above we cannot able to perform surgery. In spite of giving 3-5 ml of Bupivacaine 40% of patient in group A and 21% of patient in group BF need analgesic supplements but it is lesser in group BF.

Epidualrally administered fentanyl in doses of 50-100 microgram has been shown to provide postoperative analgesia of 3-4 duration. This was similar to our duration of effective analgesia, following 25 μg dose of subarachnoid fentanyl. The patient of group A experienced more pain as compare to group B. time of giving analgesic injection was 12±4.35 -min in group A and .146±.85- min in group BF. Group BF patients were more comfortable in our study, and that result was similar to most of the studies.

One of the biggest limitations of our study is that patient was not interested in ambulation on the day of surgery because of psychological fear of pain and opening of stitches. In our study, two patients belong to group BF, receiving 25 μg fentanyl complain of pruritus which is similar to the report of Hunt et al. We did not observe significant respiratory depression or sedation except in one patient. Gang TJ et al observed that Fentanyl 20 μg was added to Bupivacaine, it reduces Intraoperative nausea and vomiting and prolongs anaesthesia. In our study 40% of patients from group A and 25% patients from group BF felt nausea and having vomiting. It is reduced in group BF.

Intra operative nausea and vomiting occurs in as many as (30%) of gallbladder surgery. It was more in group A 40% and 25% in group B it could be mainly related to peritoneal traction. M Anullang et al and Dahlgren et al observation is same. For cesarean section intrathecal dose of hyperbaric Bupivacaine is 12 to 15 mg. Cesarean delivery requires traction of peritoneum and handling of intraperitoneal organs, resulting in intraoperative visceral pain. With higher doses of hyperbaric bupivacaine, incidence of intraoperative visceral pain associated with higher blocks is reduced.

Goel et al found 12.5 μg Fentanyl provide better surgical anaesthesia but increased urinary retention, which is a significant side effect of spinal opioids, but fentanyl appears to have a more favorable result, Liu et al. found no increase in time of first voiding. Ben David et al reported no significant difference in time to urination with addition of 10 μg IT fentanyl. In present study group A have taken 8.5 hours (510±15 min) and group BF had taken 10.3 hours (618±34 min). Thus, there was significant increase in time in group BF. Manjula et al study showed voiding time was 330 min, in our study the voiding time of group A 510±15 min and Group BF was 618± 34 min. which were significantly higher as compare to other studies. It could be due to increase volume of bupivacaine used for the reliability of the block. Gurbet et al found that 25 μg IT fentanyl reduced the analgesic requirement similar to our study. Belzarana used 0.5 or 0.75 μg/kg IT fentanyl for caesarean delivery and Singh et al used 25 μg IT fentanyl for lower extremity surgery.

According to our experience if Bupivacaine 15 mg is diluted with 0.5 ml of saline to make a volume of 3.5 ml often results in failed block because we are giving high spinal and performing gall bladder surgery in spinal anaesthesia. At our centre the gall bladder surgery are performed under spinal anaesthesia as there is lack of staff for post-operative monitoring cost is another consideration as our centre caters patients from very poor socio economic status.

The ability of a subject to flex at the hip, extend the knee and planter flex the ankle, big toe have been used as an end point to analyse recovery from motor blockade, but we cannot discharge the patients on that basis, sometime due to mild pain and fear to open the stitches, most of the patients did not cooperate. The time taken by patient to ambulate and completely resolve analgesia after spinal anaesthesia with Group A and Group BF were equal, the cause could be that patient were not interested to ambulate on day of surgery and at night we cannot insist the patient to ambulate, and next day of surgery all patients were able to ambulate but they need support only due to fear.

CONCLUSIONS

Bupivacaine with intrathecal fentanyl 25 μg produces a satisfactory surgical block, significantly decreases the need of analgesic supplementation, but increases the voiding time, early ambulation occurs in this group. There are no side effect of intrathecal fentanyl. It is very good for patients. Thus, overall effect of Bupivacaine and Fentanyl is superior to Bupivacaine alone, apart from positive effects of fentanyl, it decreases the requirement of bupivacaine and has no side effects.
