HOW TO CITE THIS ARTICLE:

ABSTRACT: Macrodystrophia lipomatos is a rare cause of congenital macrodactyly, characterized by progressive proliferation of all mesenchymal elements, with a disproportionate increase in fibroadipose tissue. This developmental anomaly is reportedly more common in the foot than in the hand, with a predilection for the plantar and median nerve distribution. We present a case of MDL of the hand, one of which had an unusual nerve territory distribution, making clinical diagnosis difficult. Diagnosis was however made on the basis of radiography and colour Doppler was negative.

KEYWORDS: Macrodystrophia lipomatos, macrodactyly, imaging.

INTRODUCTION: Macrodystrophia lipomatos (MDL) presents as localized gigantism of the hand or foot and comes to clinical attention because of cosmetic reasons, mechanical problems secondary to degenerative joint disease, or development of neurovascular compression due to large osteophytes.[1] Radiological investigations, especially MRI, help to make a definitive diagnosis noninvasively and to differentiate it from other causes of macrodactyly.

CASE REPORT: A 9-year-old, right-hand-dominant female child presented with a progressive disproportionate enlargement of the thumb of her right hand since 1 year of age. The patient denied having any pain or neurovascular symptoms and there was no family history of extremity gigantism. On physical examination, a non-tender, soft tissue mass was palpable on the volar aspect of the enlarged thumb [Figure 1]. There were no overlying cutaneous changes, pitting edema, or bruit. The patient was able to use the hand well and had an adequate grip. A plain radiograph demonstrated soft tissue swelling along the volar aspect of the thumb, an enlarged distal phalanx of the thumb [Figure 2]. An MRI with a 1.5-T unit demonstrated increased fatty tissue along the palmar aspect thumb, extending up to the thenar eminence.

It was seen as a hyper intense area on T1W images with intermediate signal on T2W images [Figure 3]. The underlying bones revealed normal signal intensity and intact periosteum. Contrast MDCT angiogram of the right forearm and hand was performed. Abnormal excessive subcutaneous fat of the thumb partially extending into the palm is noted. There is no evidence of any abnormal leish of vessels to suggest a vascular malformation or any aneurysm noted in this region. Prominence of the superficial veins of the thumb and the hand is noted. High resolution of right hand performed with 5-17MHz linear transducer shows soft tissue swelling involving thenar eminence and thumb. [Figure 4]

DISCUSSION: MDL is an uncommon congenital, nonhereditary, localized gigantism involving the digits or extremities. This term was first used by Feriz in 1925 to describe unilateral overgrowth of the lower limb.\(^2\) Though the exact etiology of MDL is not known, various hypotheses exist, including alteration of somatic cells during limb bud development and disturbed fetal circulation.\(^3\)

MDL usually presents at birth and may be associated with anomalies like syndactyly, polydactyly, brachydactyly, or clinodactyly.\(^4\) Association with small osseous protuberances, which
CASE REPORT

resemble osteochondromas and lipomas, in other parts of the body has also been reported.[5] The disease is almost always unilateral, with an equal incidence in males and females.[6] The growth velocity may differ from digit to digit and the abnormal growth usually ceases at puberty. The lower limb is more frequently involved than the upper limb. The abnormal area is usually along a specific sclerotome. The second and third digits of the hands and feet are most frequently involved, corresponding to the median nerve and medial plantar nerve supply in the upper and lower limbs, respectively.[7]

Involvement of the ulnar nerve distribution, is extremely unusual.[4] The soft tissue overgrowth is most marked at the distal ends of the digits on the volar aspect and results in dorsal angulation of the involved digit.

Different imaging modalities, such as plain radiography, USG, CT scan, and MRI, have a role in the evaluation of MDL. Plain radiography reveals hypertrophy of soft tissue and bone, with translucencies in the soft tissue due to increased adipose tissue. The phalanges, especially the distal phalanx, are elongated, broad, and splayed, sometimes giving rise to a mushroom-like appearance. Secondary osteoarthritic changes like joint space narrowing, sub chondral cysts, and osteophytes often develop in adolescence or early adulthood.[1] Both USG and CT scan can be used to demonstrate the proliferation of fat along the nerve territory.[8,9] MRI easily demonstrates the excess fibrofatty tissue, which has signal characteristics similar to subcutaneous fat, i.e., high signal on T1W, intermediate signal on T2W, and low signal on fat-suppressed sequences. The fat in MDL is not encapsulated. The fibrous strands within the fatty tissue are seen as low-signal-intensity linear strands on T1W images.

The differential diagnoses of MDL and macrodactyly include neurofibromatosis, hemangiomatosis, lymphangiomatosis, Proteus syndrome, and fibrolipomatous hamartomas. Neurofibromas show marked hyperintensity on T2W images and are seen in close relation to nerves. A positive family history, presence of cutaneous lesions, and bilaterality favor neurofibromatosis, while hypertrophy along a nerve territory, unilaterality, and demonstration of fat within the nerve sheath on MRI favor MDL.[10] Lymphangiomas are hyperintense to muscle on T1W and hyperintense to fat on T2W images. Clinically, diffuse swelling and pitting edema are found.[8] In hemangiomatosis, a bruit may be palpable clinically and, on MRI, long TR/TE sequences show a septate configuration of high-signal-intensity channels, corresponding to the vascular channels and fibrous strands found in hemangiomas. Osseous growth is not seen in both lymphangiomatosis and hemangiomatosis.[8]

Proteus syndrome presenting with hemihypertrophy may simulate MDL, but associated abnormalities like calvarial changes, pulmonary cysts, pigmented nevi, and intra-abdominal lipomas help to arrive at the correct diagnosis. Some consider MDL to be a localized form of Proteus syndrome. Fibrolipomatous hamartoma (FLH) of nerve is a rare tumor-like condition in which mature fat infiltrates the neural sheath, with the majority of the lesions occurring in the median nerve. Pathologically, in FLH, the deposition of fat is within the nerve sheath, while in MDL it occurs throughout the involved part of the digits/extremity. However, MDL may be an associated feature of FLH in as much as 30–66% of cases.[11] FLH may show a speckled appearance on MR, correlating with its histologically known architecture, i.e., neural fascicles separated by fat and connective tissue.

In conclusion, determination of the cause of macrodactyly is clinically difficult due to the many possible etiologies. However, appropriate imaging, particularly with MRI, can make the determination of the underlying process easier and can be of great help in arriving at a correct
diagnosis. Imaging helps in differentiating MDL from other causes of localized hemihypertrophy, which have different prognoses, complications, and treatment.
