PRESENTATION OF CASE

A 60-year-old male presented with swelling in the left submandibular region and cervical region. He was investigated and was found to have high-grade B-cell Non-Hodgkin Lymphoma in 2010. He received six cycles of R-CHOP (Rituximab, cyclophosphamide, doxorubicin, vincristine, prednisone) chemotherapy. He was symptom-free till 2015. In February 2015, he presented with complaints of severe headache and signs of increased intracranial tension. Contrast-enhanced computed tomography revealed homogeneously enhancing lobulated mass lesions, three in number, with small central ill-defined hypoattenuating areas noted in right supratentorial region predominantly in the subependymal regions along the right lateral ventricle around the frontal horn, and occipital horn with near total obliteration of right lateral ventricle and also in the subcortical white matter region of right parietal lobe [Figure 1]. He had no evidence of significant lymphadenopathy in the neck, thorax, abdomen, and pelvis.

CLINICAL DIAGNOSIS

Stereotactic biopsy from the lesion confirmed Non-Hodgkin lymphoma. Cerebrospinal fluid cytology was negative. Bone marrow biopsy revealed no evidence of infiltration by lymphoma. The patient was diagnosed to have isolated CNS relapse and was treated with five cycles of chemotherapy with R-MPV (Rituximab, methotrexate, procarbazine, and vincristine). Post-chemotherapy imaging showed progressive disease. So, the patient was not considered for bone marrow
transplantation. He was treated with whole brain radiotherapy of 40 Gy in 20 fractions by CRT technique in October 2015 [Figure 2].

Post-radiotherapy CECT was done in November 2015 which showed complete resolution of the enhancing mass noted in the previous scan. It also showed ill-defined hypodensity in a right periventricular region adjacent to the frontal horn, trigone and occipital horns of right lateral ventricle causing mild effacement of the frontal horn suggestive of post radiation changes [Figure 3]. MRI in January 2016 showed no contrast enhancing lesion and demonstrated only posttreatment changes. PET-CT did in January 2016 also confirmed no evidence of metabolically active disease anywhere in the body.

**DISCUSSION OF MANAGEMENT**

Isolated central nervous system [CNS] relapse involving brain parenchyma in a patient with systemic non-Hodgkin lymphoma [NHL] is not uncommon. About 2% to 4% of systemic non-Hodgkin lymphoma relapses in the brain. Long-term survival is possible with systemic methotrexate based combination chemotherapy in isolated CNS relapse in non-Hodgkin lymphoma, and it is considered the current standard of care. Whole brain radiotherapy is not a preferred modality in older individuals due to its delayed neurotoxicity. However, in patients with disease not responding to chemotherapy, whole brain radiotherapy needs to be considered. One of the patients who progressed and deteriorated with chemotherapy was treated with whole brain radiotherapy. Radiotherapy was the messiah for this patient, and he had a complete recovery with whole brain RT.

There are three patterns of central nervous system involvement in non-Hodgkin lymphoma: primary, secondary and isolated CNS relapses. In primary CNS lymphoma, the disease is limited to the brain parenchyma, leptomeninges, eyes, and the spinal cord; whereas in secondary CNS lymphoma, there is concomitant systemic and CNS involvement, often involving the leptomeninges. Isolated CNS relapse is defined as involvement of CNS in a known systemic non-Hodgkin lymphoma cases but with no evidence of systemic disease.

Central nervous system [CNS] relapse with systemic non-Hodgkin lymphoma may involve the brain parenchyma, spinal cord, leptomeninges, or eyes. Central nervous system involvement may be part of disease progression or as a recurrence of systemic disease. Isolated CNS relapse with systemic NHL with no evidence of disease outside the central nervous system is rare, and it occurs in approximately 2% to 4% of patients. There are no standard guidelines for the management of isolated CNS relapse case. In general, pathologic documentation by stereotactic biopsy is mandatory when imaging studies suggest Non-Hodgkin lymphoma in brain parenchyma. In our patient, stereotactic biopsy revealed Non-Hodgkin lymphoma confirmed by immunohistochemistry markers.

Systemic high-dose methotrexate based combination chemotherapy with or without whole brain radiotherapy is recommended for any CNS lymphoma. The role of radiotherapy in the management of CNS lymphoma is limited by insufficient local control and delayed neurotoxicity in terms of gait and memory disturbances. Nelson et al studied whole brain radiation therapy alone in the management of primary CNS lymphoma. The dose delivered was 36-40 Gy. The overall response rate was 90% but a median overall survival was only 11.6 months and 60% of patients developed progression of lymphoma within the irradiated field. Data suggest that high-dose chemotherapy with autologous stem cell transplant is feasible and efficient in patients with CNS relapses. In the study patient, high dose Methotrexate-based chemotherapy showed resistance, and in fact, the disease progressed on treatment. Performance status deteriorated further due to high dose chemotherapy schedule. So the patient was not considered for any further intensive chemotherapy and stem cell transplantation. Once the patient was stabilised, he was considered for whole brain radiotherapy to a total dose of 40 Gy in 20 fractions. Radiotherapy period was uneventful. Follow-up contrast-enhanced CT and MRI showed no evidence of disease in the brain parenchyma.

PET-CT was done three months post-radiotherapy, and it showed no signs of disease anywhere in the body. Now the patient is on regular follow-up. Although longer follow-up is required to establish the role of WBRT, our patient has a disease-free interval of 10 months till now. WBRT should be considered in patients not responding to standard chemotherapy.

**Conclusion**

Isolated CNS relapse in Non-Hodgkin lymphoma is quite rare. High-dose Methotrexate-based chemotherapy forms the standard of care for most cases of CNS relapses, but whole brain radiotherapy can still be a messiah for resistant cases. Complete response is possible with whole brain radiotherapy. However, the duration of sustained response can be ascertained only on long term follow-up.

**FINAL DIAGNOSIS**

Stereotactic biopsy revealed Non-Hodgkin lymphoma confirmed by Immunohistochemistry markers.
