ABSTRACT

BACKGROUND
Hydatid cyst may occur in any part of the Liver. Surgery remains the gold standard in terms of treatment of patients of hydatid cyst in liver. Laparoscopic treatment is safe in hydatid liver disease.

Objective- To evaluate the safety and feasibility of laparoscopic treatment of hydatid cyst of liver.

MATERIALS AND METHODS
The study included 30 patients who had undergone laparoscopic management of hydatid liver disease at civil hospital, Jalandhar from Nov. 2007 to Sept. 2012 and at Punjab Institute of Medical Sciences (PIMS), Jalandhar from Sept. 2012 to June 2016. Age, sex, duration of surgery, surgical morbidity, hospital stay, recurrence of disease were noted to evaluate the safety and feasibility of this procedure.

RESULTS
Laparoscopic treatment was performed on thirty patients (Eighteen males and twelve females) with conversion to open surgery necessary in one male patient due to dense intra-abdominal adhesions. Mean age was 44 years (range 18-70 years). Size ranged from 8-12 centimetres with mean diameter 9.5 centimetres. There was no disease or procedure-related mortality. Hospital stay was 2-4 days. Three patients had external biliary fistula resulting from communication between cyst and the biliary tree which healed spontaneously without intervention after 26 days, 40 days and 2 months. There were two recurrences in the one-year followup period.

CONCLUSION
Laparoscopic management of hydatid cysts of liver can be performed safely and successfully with certain precautions. Laparoscopic surgery of hepatic hydatid disease has been increasingly popular and has undergone a revolution parallel to the progress in laparoscopic surgery.[1]

KEYWORDS
Laparoscopic, Liver, Hydatid cyst.

Figure 1

LIFE CYCLE OF HYDATID CYST

Hydatid disease is endemic mainly in the Mediterranean countries, Middle East, South America, India, Northern China, Australia and Far East and sheep raising areas.[2,3,6] Hydatid disease is a zoonotic infection caused by adult or larval stages of Echinococcus granulosus. Liver is the most commonly affected organ (75%), followed by lungs, spleen, kidney, brain, etc. The typical lesion is a cystic cavity, filled with clear hydatid fluid containing live protoscoleces. Hydatid cyst has two layers: The ectocyst or pericyst, a dense fibrous outer layer and an inner layer called endocyst or the germinative membrane from which brood capsules containing protoscoleces proliferate towards the cystic cavity. Actually, the ectocyst consists of compressed liver cells and fibrotic tissue, which is a host reaction to the presence of the parasite and does not belong to the parasite but to the host liver. Therefore, the only live material, which should be the target of any treatment modality, is the germinative membrane and the fluid it contains together with live and infective protoscoleces or daughter cysts.

Surgery remains the gold standard treatment for patients with echinococcosis despite significant economic costs, advances in medical treatment, and interventional radiology.[5,7] The aims of surgery are complete evacuation of the cyst without spillage followed by sterilisation and obliteration of the cavity. Laparoscopic approach is a suitable surgical technique to achieve these aims. In last two decades, laparoscopic treatment of hydatid cyst of liver has become...
increasingly popular and has undergone a revaluation parallel to the progress in laparoscopic surgery.\(^1\) Different reports of laparoscopic surgery of liver hydatid cyst exist, some are case reports\(^{[8-13]}\) and some are series of less than ten to fifteen cases.\(^{[14-16]}\)

Still controversies about the role of laparoscopy in the management of liver hydatid cyst exist worldwide including laparoscopic access, those cysts with calcified walls, and also the patients with recurrent disease may not be suitable for laparoscopic surgery due to possibility of dense intra-abdominal adhesions as well as cysts with preoperatively recognised biliary communication.

With developments in laparoscopic surgery, there have been successful attempts to treat hydatid cysts of liver with added advantage of this new technique.\(^{[17-23]}\)

**MATERIALS AND METHODS**

The study included 30 patients who have undergone laparoscopic management of hydatid liver disease at civil hospital, Jalandhar from Nov. 2007 to Sept. 2012 and at Punjab Institute of Medical Sciences (PIMS), Jalandhar from Sept. 2012 to June 2016. Age, sex, duration of surgery, surgical morbidity, hospital stay, recurrence of disease were noted to evaluate the safety and feasibility of this procedure. The disease was diagnosed by abdominal ultrasonography, CT scan and confirmed by serological examination. X-ray chest done in all patients. Our inclusion criteria were- solitary cyst located in segment 3, 4, 5, 6 and 8 with diameter between 8-12 centimetres and with no evidence of calcification, preoperative biliary communication or cyst infection. Exclusion criteria were- multiple hydatid cysts or cyst located in segment 1, 2 and 7 as they are the blind areas for laparoscopic procedures. Intraparenchymal location of cyst was excluded as well. There were six men and five women. The mean age was 44 years (range 18-70 years). The mean cystic diameter was 9.5 centimetre (range 8-12 centimetre). Eleven cysts were located in segment 4, eight cysts located in segment 5, six cysts located in segment 6 and five located in segment 8. After the diagnosis, medical treatment with Albendazole 10 mg/kg (400 mg BD) per day was given for 3 weeks before surgery in all patients. We planned a laparoscopic surgical approach. Pre-operative liver function tests were normal in all the patients.

We used three 10 mm & one 5 mm trocars. The cyst was approached laparoscopically by using same hydatid asepsis techniques as in open surgery. Under general anaesthesia, patient was placed in supine position, surgeon and camera assistant standing on the left side of the patient with the assistant & scrub nurse standing on right side of the patient. Using CO\(_2\) pneumoperitoneum pressure of 12 mmHg was obtained. Diagnostic laparoscopy was performed to localise the cyst through a 10 mm infraumbilical port. A 10-mm port used at the epigastrium as a working port and an additional 10 mm port at midclavicular right subcostal through which Palanivelu Hydatid System (PHS) was used and another 5 mm port on right lateral side depending on site of cyst. Roll gauzes soaked in hypertonic saline (20% NaCl) placed around the cyst and an Endobag made from vacuum suction with internal sterile plastic cover put into abdomen through 10 mm epigastric port. More hypertonic saline was injected with Veress needle over the roll gauzes which surround the cyst.

![Figure 3. Roll Gauzes Soaked in Hypertonic Saline (20% NaCl) Placed Around the Cyst](image3)

![Figure 4. Using Palanivelu Hydatid System [PHS]](image4)

Then PHS introduced directly into cyst and connected to suction for continuous vacuum suction. Irrigation of the cyst done with hypertonic saline which was allowed to remain for 15 minutes and changed 4 to 5 times. A portion of cyst wall excised for pathological examination.

The germinative layer and hydatid daughter cysts were sucked out with 10 mm suction and removed with care and placed in Endobag (Fig. 5) and retrieved through epigastric port. Then laparoscope was inserted into cyst to exclude any biliary communication or retained daughter cysts. The cyst
cavity was irrigated with hypertonic saline several times. Pericystectomy was performed using electrical curved scissors and a spatula. Gauze pieces were removed through 10 mm epigastric trocar. The pericyst cavity was obliterated with omentum after putting a suction drain into the cavity.

Figure 5. Extraction of Endobag with Contents

Oral liquid intake was allowed on same day of surgery after 6 hours. If no bile is draining through Romovac drain, drain is removed 48 hours post-operation. All the patients did well postoperatively and discharged on 3rd or 4th day. The patients were planned to be followed up at one month, three months, six months and then yearly for ultrasonography and serology.

Albendazole 10 mg/kg was started from postoperative day 1 and continued for 21 days, then a gap of 14 days given. 3 cycles recommended to prevent recurrence.

RESULTS
In all the cases diagnosis was confirmed by ultrasonography, CT scan, Serology and all the patients had normal liver function tests. Laparoscopic treatment was performed on thirty patients (eighteen males and twelve females) with conversion to open surgery necessary in one male patient due to dense intra-abdominal adhesions. There was no disease or procedure-related mortality. Hospital stay was 2-4 days. Three patients had external biliary fistula resulting from communication between cyst and the biliary tree which healed spontaneously without intervention after 26 days, 40 days and 2 months. There were two recurrences in the one-year follow-up period.

To prevent recurrence all the patients were put on Albendazole 10 mg/kg started from postoperative day 1 and continued for 21 days, then a gap of 14 days given. 3 cycles were recommended.

DISCUSSION
Hydatid disease is characterised by worldwide distribution and frequent hepatic involvement. In classical open surgery, overall postoperative mortality ranges between 0% to as high as 7.5% in the early period. Morbidity is also observed in 4-25% of the cases. It is better and safe to use laparoscopic surgery in treatment of hydatid liver with less morbidity, mortality, and shorter hospital stay and recurrence rate in comparison with open technique. It also prevents intraperitoneal spillage of cyst contents. Biliary communications are reportedly common in hydatid disease.

Laparoscopic approach offers better visual control of the cyst cavity under magnification, which allows better detection of small open bile ducts that leak bile. These can be taken care by direct suturing or cauterisation and better visualisation of the remains of germinative layer of the cyst.

The procedure is contraindicated in patients with secondary infected cysts, or suspected biliary communication (Bile-stained aspirate), owing to increased risk of complications. Posterior cysts, more than three cysts, cysts with thick & calcified walls are also contraindicated.

Inactivation of cyst with 20% NaCl (hypertonic saline), removal of the cyst contents without contaminating the abdomen, followed by appropriate management of any remaining cavity. The cyst is approached laparoscopically by using same hydatid aseptic techniques as in open surgery. We have converted one laparoscopic procedure to open in one male patient due to dense adhesions. Patient selection depending on site of cyst is important in early experience as advocated by many authors. Draining of remaining cyst cavity for 48 hours by Romovac drain helps to obliterate cavity and prevents biliary peritonitis if bile leak is there. We always used the technique of obliterating the cavity by plugging the greater omentum. PHS is successful in preventing spillage, evacuating the contents of hydatid cysts, performing transcystic fenestration and dealing the cyst-biliary communications. We used this suction cannula to evacuate the cyst contents. Advances in laparoscopic technology and with the introduction of harmonic scalpel resection is possible in more complicated cysts. With limitation of harmonic scalpel, we worked cautiously to avoid unnecessary risks to our patients of liver hydatid cyst.

CONCLUSION
Laparoscopic management of hydatid cysts of liver can be performed safely and successfully with certain precautions. It has been increasingly popular and has undergone a revolution parallel to the progress in laparoscopic surgery.
