ABSTRACT

BACKGROUND
Currently available literature highlights association of hypovitaminosis D with chronic diseases such as diabetes mellitus and systemic hypertension, but there are very few studies on role of vitamin D in pulmonary tuberculosis (PTB) in our population.

MATERIALS AND METHODS
Vitamin D levels in 180 cases of newly diagnosed active pulmonary tuberculosis (Both sputum positive and sputum negative) and 180 age and gender matched healthy controls were estimated. 25 Hydroxy vitamin D3 levels were estimated by sensitive fully automated Chemiluminescent Immunoassay (CLIA) technique. Vitamin D3 levels were categorised as sufficient, insufficient and deficient. Patients were followed for six months for final outcome (Tuberculosis cured/not cured).

RESULTS
Out of 180 cases, 95 (52.78%) were sputum positive and the remaining 85 (47.22%) were sputum negative. Mean vitamin D levels were significantly low in cases (12.23 ± 5.99 ng/mL) as compared to controls (18.7 ± 10.19 ng/mL) (p value <0.001). Among the 180 cases, 158 (87.78%) had vitamin D deficiency, 18 (10%) had vitamin D insufficiency; whereas among controls, 105 (58.33%) had vitamin D deficiency, 46 (25.56%) had vitamin D insufficiency. The prevalence of vitamin D deficiency and vitamin D insufficiency was higher among cases compared to controls (p-value < 0.05).

CONCLUSION
There is significant deficiency of Vitamin D in patients with PTB. More prospective designed studies are needed to firmly establish the direction of association between PTB and vitamin D deficiency (VDD).

KEYWORDS
Vitamin D Deficiency, Pulmonary Tuberculosis.

MATERIALS AND METHODS
This case control study was carried out at tertiary care teaching hospital during the period of October 2012 to July 19, 2014. Total 180 cases of newly diagnosed PTB (by sputum microscopy and chest x-ray) were included. 180 age and gender matched controls were recruited from healthy visitors and relatives of patients. Both cases and controls were subjected for clinical history with particular reference to...
symptoms of hypovitaminosis D such as frequent musculoskeletal pain and proximal muscle weakness, physical examination and vitamin D3 level using fully automated Chemiluminescent immunoassay (CLIA) technique. Routine necessary blood investigations of cases i.e. complete blood count, random blood sugar, renal function test (blood urea, serum creatinine), serum calcium, liver function test (SGOT, SGPT, serum bilirubin, serum albumin) were done. The blood samples of patients for estimation of vitamin D were taken before starting anti-tuberculous treatment. PTB patients who were otherwise prone for vitamin D deficiency like malabsorption, liver or renal disorders, diabetes mellitus, systemic hypertension and those on drugs which can reduce vitamin D levels or antagonise its actions were excluded from this study. Those who were predisposed to develop tuberculosis due to other obvious causes also were excluded (HIV infection, diabetes mellitus, on immunosuppressive therapy, severe protein energy malnutrition). Patients were followed up for 6 months for final outcome of pulmonary tuberculosis (i.e. cured or not cured). Patients who completed 6 months of anti-Koch's treatment (AKT) and were sputum negative and symptom free were considered "cured". Whereas patients who had treatment failure (i.e. sputum positive even after 2 months, 5 months of AKT) and those who died were considered "not cured". Participants not giving valid written consent were excluded from this study. The study was approved by institutional ethics committee. The previous published studies have documented 70 to 90% vitamin D deficiency in general population in India. The sample size for present 1:1 matched case-control study was calculated using Odds ratio of 2, alpha error of 0.05, power of study as 80% and percentage exposed among controls as 70%, thus justifying our sample size of 180 cases.

Statistical Analysis
Data was analysed using the Microsoft excel program. Data was compared using student's t-test for continuous variables and chi square test for categorical variables as appropriate. P-value ≤ 0.05 was considered as significant.

RESULTS
The mean age of cases (n=180) in our study was 38.13 ± 16.24 years. Majority of the cases were young i.e. 85 (47.22%) from 21-40 years age group. Male (n=105) to female (n=75) ratio was 1.40:1. Majority of the cases had symptoms of fever (91.67%), cough with expectoration (91.11%) and loss of appetite (70%). Less common symptoms were chest pain, haemoptysis, breathlessness and weight loss. Among cases, 95 (52.78%) were sputum positive and the remaining 85 (47.22%) were sputum negative. Mean vitamin D levels were significantly low in cases (12.23 ± 5.99 ng/mL) as compared to controls (18.7 ± 10.19 ng/mL) (p value <0.001). Mean vitamin D levels were significantly lower in sputum-positive cases (10.90 ± 6.82 ng/mL) as compared to sputum-negative cases (13.74 ± 6.08 ng/mL) (p value < 0.05). According to serum vitamin D levels, cases and controls were divided into normal, insufficiency and deficiency groups (Table 1). Symptoms of hypovitaminosis D were present only in 21.59% of the cases with hypovitaminosis D (38 out of 176) as compared to 3.97% of controls with hypovitaminosis D (6 out of 151). There was no significant difference in vitamin D level in clinical outcome. (Table 2).

DISCUSSION
In this study, we had observed statistically significant association between PTB and hypovitaminosis D. Kelechi EN et al10 in their meta-analysis had reviewed seven primary studies and found that patients with tuberculosis had lower serum levels of vitamin D than healthy controls matched on sex, age, ethnicity, diet and geographical location. The pooled effect size in random effects meta-analysis was 0.68 with 95% CI 0.43-0.93. This 'medium to large' effect represents a probability of 70% that a healthy individual would have higher serum vitamin D level than an individual with tuberculosis if both were chosen at random from a population. PK Sasidharan et al11 in his study from Kerala and Najeeha Talat et al12 from Pakistan also found significant vitamin D deficiency in tuberculosis patients as compared to healthy controls. Another study from India by Rathored et al7 concluded that vitamin D receptor gene polymorphism and hypovitaminosis D may predispose to MDR-TB. They also found that vitamin D level was significantly lower in MDR-TB as compared to drug-sensitive TB and disease severity, time to sputum smear and culture conversion were inversely correlated with vitamin D levels. In our study, vitamin D was significantly lower in sputum-positive cases as compared to sputum-negative cases and as the sputum smear grade of AFB increased the vitamin D levels decreased further.

We also observed that asymptomatic hypovitaminosis D is highly prevalent in apparently healthy individuals. Several published studies13,14,15 had confirmed the possibility of wide spread deficiency of vitamin D in India, in spite of being a sunny country. The major reasons for low vitamin D in our country are 1) poor dietary intake of vitamin D and not decreased sun light exposure, 2) reduced cutaneous biosynthesis of vitamin D could be due to the increased melanin in skin, 3) poor intake of vegetables, which is a very common issue in most people of our country, and the resultant magnesium deficiency might lead to reduced Parathyroid hormone (PTH) secretion and the consequent reduction of 1-hydroxylation of vitamin D.16

There is scarcity of data regarding effect of outcome of PTB in hypovitaminosis D patients from our country.17 Though sample size was small, we did not find any significant difference in vitamin D level between cured PTB cases and non-cured PTB cases.

Vitamin D has been attributed an important role in host immune defence against Mycobacterium tuberculosis.18 It has been shown by Liu et al19 that vitamin D supplementation

results in increased expression of anti-microbial peptide ‘cathelicidin’ in the macrophage culture, which could result in killing of the intracellular Mycobacterium tuberculosis. This is a potential mechanism which could logically explain role of vitamin D in enhancing immunity in patients with tuberculosis.

There is a long history of using vitamin D to treat tuberculosis with some apparent success. Finsen, in his Nobel prize winning discovery, successfully used UVB rays to treat the cutaneous form of tuberculosis.20 Dowling and Prosser Thomas reported the treatment of tuberculosis with oral vitamin D in 1946.21 Vitamin D supplementation is being tried as an adjuvant to chemotherapy in PTB, enhancing antimicrobial response and accelerating clearance of bacilli in some patients.22,23

We have some limitation of our study. We are unable to do detailed dietary assessment of the intake of vitamin D in cases and controls. We have not excluded smoking persons from this study. Smoking, being a risk factor for PTB and theoretically can decrease calcium absorption thereby altering vitamin D level, can be a confounding factor.24 25 Being a cross sectional study, the temporality between PTB and vitamin D deficiency could not be established.

Implication of this study is that all PTB patients should be screened for vitamin D deficiency.

CONCLUSION
There is significant deficiency of Vitamin D in patients with PTB. Asymptomatic vitamin D deficiency is common in apparently healthy persons. Larger prospective studies are necessary to firmly establish the direction of the association between vitamin D deficiency and PTB. Randomised control trials are needed for determining role of vitamin D supplementation in PTB treatment.
