ABSTRACT

BACKGROUND

Osteoarthritis (OA) is a degenerative joint disease, occurring primarily in older persons. It is the fourth leading cause of Years Lived with Disability (YLD). OA has become a major health problem now; not only because of its increasing prevalence worldwide but also because of its frequent association with cardiovascular disease, the leading cause of death in industrialised countries. There is growing evidence that OA is not simply a disease related to aging or mechanical stress of joints, but rather a “metabolic disorder” in which various interrelated metabolic derangements contribute to the initiation and progression of the disease process. It is a misnomer to label osteoarthritis as a purely degenerative arthritis. It is now clear that an active genetic and proteomic profile suggests inflammation. The cytokine milieu is similarly inflammatory and parallels that found in the Metabolic Syndrome (Met S). Met S is a constellation of metabolic risk factors that directly promotes the development of cardiovascular disease and increases risk for developing Type 2 diabetes.

This study is aimed to determine the prevalence of metabolic syndrome in patients with OA knee.

MATERIALS AND METHODS

It is a descriptive study, which was conducted at Lifestyle diseases management clinic of the Department of Physical Medicine and Rehabilitation, Govt. Medical College, Kozhikode; including 150 subjects with Osteoarthritis of knee as cases and 80 subjects without Osteoarthritis as controls and the prevalence of metabolic syndrome was studied in both these groups.

RESULTS

The study observed that metabolic syndrome was present in 72% of cases and only in 37.5% among control group.

CONCLUSION

There is significant association between osteoarthritis of knee and metabolic syndrome (p value of 0.000). The association between metabolic syndrome with osteoarthritis of knee was more in females. Among the metabolic profile abnormalities; there was significant association of hypertension with osteoarthritis. The association between hypertension and osteoarthritis of knee was also more among females.

KEYWORDS

Metabolic Syndrome; Osteoarthritis of knee.

BACKGROUND

Osteoarthritis (OA) is a degenerative joint disease, occurring primarily in older persons, characterised by erosion of the articular cartilage, formation of osteophytes; which are hypertrophy of bone at the margins, subchondral sclerosis and a range of biochemical and morphologic alterations of the synovial membrane and joint capsule. It is the most common type of arthritis affecting 27 million adults in US.

In industrialised societies, OA is the leading cause of physical disability, increases in healthcare usage and impaired quality of life affecting 60% - 70% of the population older than 60 years.3 The worldwide prevalence estimate for symptomatic OA is 9.6% among men and 18% among women. It is the fourth leading cause of Year Lived with Disability (YLD).4 In India, the overall prevalence of osteoarthritis in the elderly is 56.6%5; OA is more common in females as compared to males (70.1% vs. 41.6%).6

Osteoarthritis is rapidly becoming a significant medical and financial burden in a world whose population is ageing.7 It affects both working and retired individuals and has a broad economic burden on health. The pathophysiological mechanisms of OA are under debate, but there is general agreement that biomechanics and increased dynamic loading of the joint are involved.8 Various risk factors such as ageing, female gender, obesity, repetitive joint loading9 (occupational and leisurely physical activities) and previous knee injury have been reported.10-12
Above all obesity is the most important risk factor, because it remains a matter of possible improvement. There is debate about how obesity contributes to knee OA. It is most commonly considered that excessive and/or misdirected biomechanical load stimulate excess osteoblasts or chondrocyte biosynthesis in the bone or cartilage. On the other hand, the association between obesity and knee OA as well as finger OA has been reported. Another theory is that joint health is affected by a generalised negative metabolic environment reflecting a systemic inflammatory response or response to the secretory products of adipose tissues. However, there is little consensus regarding the latter theory.

There are evidences that OA is not simply a disease related to aging or mechanical stress of joints, but rather a "metabolic disorder" in which various interrelated lipid, metabolic and humeral mediators contribute to the initiation and progression of the disease progression. Indeed, OA is linked not only to obesity but also to other cardiovascular risk factors namely diabetes, dyslipidaemia, hypertension and insulin resistance. It is actually a misnomer to label osteoarthritis as a purely degenerative arthritis. It is now clear that an active genetic and proteomic profile suggests inflammation. The cytokine milieu is similarly inflammatory and nearly parallels that found in the metabolic syndrome.

Two main theories have been proposed to explain this association between obesity and OA: the biomechanical and the systemic/metabolic. The biomechanical hypothesis proposes that obesity leads to an increased loading of the (knee) joints beyond their capabilities (due to the increased body weight). Mechanical overload represents a direct physical insult to the cartilage matrix. Additionally, mechanical forces are transmitted to the cells and transformed into intracellular signals, triggering a variety of cellular responses including the release of paracrine or autocrine factors. With increased mechanical stress, cells are overstrained and fail to perform adequately.

The systemic/metabolic hypothesis proposes that metabolic factors related to obesity act directly or indirectly on chondrocytes leading to the increased risk for developing OA. Several studies suggest that adipokines (proteins synthesised and secreted mostly by adipocytes) are the major factors linking obesity to OA. Leptin, the prototypic adipokine, has been found in cartilage of OA patients and shows biologic activity on chondrocytes. It has been shown to act as a pro-inflammatory cytokine and a catabolic factor in cartilage metabolism via induction of MMPs. Conversely, it might also demonstrate anabolic effects through the stimulation of proteoglycan and collagen synthesis and the induction of growth factors. Visfatin is one of the adipokines, which has been recently studied as a pro-degradative mediator for cartilage. Adiponectin, negatively associated with body mass index, is negatively associated with progression of hand OA.

A third (indirect) effect of obesity is the induction of a (latent) diabetic metabolic state in the obese patients, overtime, enhancing for example advanced glycation end products formation within the cartilage matrix and leading to all their detrimental effects on matrix mechanoproperties and cell behaviour. Recently, diabetes was associated with risk for bilateral knee OA and hypercholesterolaemia independently associated with generalised OA.

The metabolic syndrome is a constellation of interrelated risk factors of metabolic origin-metabolic risk factors that appear to directly promote the development of Atherosclerotic Cardiovascular Disease (ASCVD). Patients with the metabolic syndrome also are at increased risk for developing type 2 diabetes mellitus. The most widely recognised of the metabolic risk factors are dyslipidaemia, elevated blood pressure and elevated plasma glucose level. Individuals with these characteristics commonly manifest a prothrombotic state and a pro-inflammatory state and so at an elevated risk for Cardiovascular Diseases (CVD). Atherogenic dyslipidaemia consists of an aggregation of lipoprotein abnormalities including elevated triglycerides and apolipoprotein B (ApoB), increased small LDL particles and a reduced level of HDL cholesterol (HDL-C) which is the good cholesterol. The metabolic syndrome is truly a grouping of cardiovascular disease risk factors, but one that probably has more than one cause. The magnitude of the increased risk of CVD can vary according to which components of the syndrome are present plus the other, non-metabolic syndrome risk factors in a particular person. The predominant underlying risk factors for the syndrome appear to be truncal obesity and insulin resistance; other associated conditions can be physical inactivity, ageing and hormonal imbalance.

The National Cholesterol Education Program (NCEP), Adult Treatment Panel III (ATP III) introduced clinical criteria for defining the metabolic syndrome. In doing so, the purpose of ATP III was to identify people at higher long-term risk for cardiovascular disease who deserved aggressive clinical lifestyle intervention early to reduce risk. The ATP III criteria did not require demonstration of insulin resistance per se. It was noted that direct measures of insulin resistance are laborious and not standardised. The ATP III criteria thus required no single factor for diagnosis, but instead made the presence of 3 of 5 factors for establishing the diagnosis.

**Criteria for Metabolic Syndrome**

1. Waist circumference ≥ 90 cm in males and ≥ 80 cm in females.
2. Fasting plasma glucose ≥ 100 or type 2 diabetes mellitus, on treatment.
3. Systolic blood pressure ≥ 130 mmHg or diastolic blood pressure ≥ 85 mmHg or hypertension on treatment.
4. In fasting lipid profile, triglycerides ≥ 150 mg/dL.
5. HDL < 50 mg/dL in females and < 40 mg/dL in males.

Presence of three of the above criteria is required for the diagnosis of metabolic syndrome. IDF recognised and emphasised ethnic differences in the correlation between abdominal obesity and other metabolic syndrome risk factors. For this reason, criteria of abdominal obesity were specified by nationality or ethnicity based on best available population estimates. For Asian populations except for Japan, thresholds were ≥ 90 cm in men and ≥ 80 cm in women.

In rehabilitation medicine, we come across a large population of patients with osteoarthritis of knee. There have been several studies citing the association of metabolic abnormalities with osteoarthritis of knee in Asian population. Unfortunately, not many studies have been conducted in this regard in the field of rehabilitation medicine in India. The findings of this study may help in improving the health status...
of every patient with osteoarthritis of knee and to reduce chances of cardiovascular diseases among them. Hence, this study is appropriate.

MATERIALS AND METHODS
The study entitled “The prevalence of metabolic syndrome in patients with osteoarthritis of knee attending Physical Medicine and Rehabilitation Department of a Tertiary Care Centre” was a hospital-based descriptive study carried out in the Outpatient Department and Lifestyle Disease Management Clinic, Department of Physical Medicine and Rehabilitation, Government Medical College, Kozhikode, during a period of one year from March 2013 - February 2014.

The study group comprised of 230 subjects including 150 cases and 80 controls; 150 persons diagnosed with osteoarthritis of knee based on clinical and radiological evidence in the age group 25 - 70 years were taken as cases and 80 persons without osteoarthritis belonging to the same age group were taken as controls.

The test group was chosen from a random selection of patients who appeared for a special knee pain clinic at the Dept. of Physical Medicine and Rehabilitation conducted every week for a period of one year. Three cases were chosen every week out of 30 patients in average who appeared in one day for 50 weeks. They were then evaluated at the Lifestyle Diseases Clinic.

Controls were selected by random selection. A simple questionnaire was distributed to patients attending the OPD with queries regarding presence of symptoms of knee pain and also their willingness to participate in the study. An average of 20 subjects without any knee pain gave consent for the study weekly and from among them 2 were randomly selected to the control sample. The process was done for 40 weeks and a control group of 80 subjects was obtained. The selected persons were evaluated at the Lifestyle Diseases Clinic.

Inclusion Criteria
1. Osteoarthritis of knee for cases.
2. Both genders.
3. Age 25 - 70 years.

Exclusion Criteria
1. History of trauma to knee.
2. Congenital deformities of lower limb.
3. Lower limb amputees.
5. Persistent neurological deficits.
6. Infective and inflammatory arthritis.

Description of Methods
Osteoarthritis of knee was diagnosed according to the ACR (American College of Rheumatology) clinical and radiologic criteria.

Clinical
1. Knee pain for most days or prior months.
2. Crepitus on active joint motion.
3. Morning stiffness lasting 30 minutes or less.
4. Age ≥ 38 years or older.

5. Bony enlargement of the knee on examination.
OA if the items 1, 2, 3, 4 or 1, 2, 5 or 1, 4, 5 are present.

Clinical and Radiographic
1. Knee pain for most days or prior months.
2. Osteophytes at joint margins on radiographs.
3. Synovial fluid typical of OA (laboratory).
4. Age ≥ 40 years or older.
5. Crepitus on active joint motion.
6. Morning stiffness lasting 30 minutes or less.

OA if the items 1, 2 or 1, 3, 5 or 1, 4, 5, 6 are present.

After obtaining an informed consent, anthropometric measurements were taken. Body weight was measured using a digital floor scale and standing height using a wall mounted stadiometer. BMI was calculated as weight in kilograms divided by height in squared meters (kg/m²). Waist circumference was measured in centimetres (cm) using a non-stretchable measuring tape just above the level of umbilicus at the end of normal expiration with the patient standing, relaxed and hands freely hanging by the side. Blood pressure was measured using a sphygmomanometer in the right upper limb in the sitting position.

The following Investigations were done
Fasting venous Plasma Glucose (FPG) and Fasting Lipid Profile (FLP).

Analytical Methods
Obesity was defined by a BMI ≥ 25 kg/m2. BMI between 18.5 kg/m2 - 22.9 kg/m2 was taken as normal and 23 kg/m2 - 24.9 kg/m2 was overweight. (In accordance with Health Ministry of India’s diagnostic cut-offs for BMI 2008).

Metabolic Syndrome
Was defined according to the consensus definition for adult Asian Indians. NCEP, ATP III recommends that three out of five clinical and/or biochemical abnormalities should be present to satisfy this labelling:
1. Abdominal obesity (Waist circumference in cm): Males ≥ 90 cm and Females ≥ 80 cm.
2. Dysglycaemia (Fasting Plasma Glucose): ≥ 100 or known case of diabetes mellitus.
3. Hypertension: Systolic BP > 130 mmHg and/or Diastolic BP > 85 mmHg or known case of hypertension.
4. In Fasting Lipid Profile, raised triglycerides ≥ 150 mg/dL.
5. Low HDL: < 40 mg/dL in males and < 50 mg/dL in females.

Statistical Analysis
All the data were coded and entered in Microsoft Excel Sheet, rechecked and analysed with SPSS-16 statistical software using descriptive statistics and odds ratio.

One hundred and fifty people with Osteoarthritis were randomly selected for the study with 80 people as controls. All were assessed for their exposure to Osteoarthritis and Metabolic Syndrome. The odds ratio of Metabolic Syndrome versus Osteoarthritis was 4.286 (95% CI 2.409 to 7.625). The results show that odds of having Metabolic Syndrome are
4.286 times greater in people with Osteoarthritis (cases) than in people without Osteoarthritis (controls). In other words, people who had Osteoarthritis were 4.286 times more likely to have Metabolic Syndrome than people who did not have Osteoarthritis.

The age distribution of the study group was between 25-70 years with mean age of 52.21 years among cases (57.32 in males and 51.33 in females) and 49.75 years among controls (52.07 in males and 49.26 in females). The mean age was comparable in both groups. The study group comprised a majority of females.

The mean BMI was 28.55 kg/m² among the cases and 29.71 kg/m² among the controls; 71% of cases and 82.5% of controls were obese. Obesity was more common among females.

**RESULTS**

Metabolic syndrome was present in 72% cases compared to 37.5% of controls. This association between metabolic syndrome and osteoarthritis of knee was found to be statistically significant with ‘p’ value of 0.000. (Table 1 and Figures 1 and 2).

The following were the Metabolic Profile Abnormalities Detected in the Study:

**Hypertension**

Hypertension was present in 59.3% of cases and 43.8% of controls and this difference was statistically significant with a p value of 0.024. Hypertension was more common among females with osteoarthritis knee compared to males and this difference was statistically significant with a ‘p’ value of 0.004.

**Dysglycæmia**

Dysglycæmia or abnormal fasting plasma glucose was present in 54% of cases and 52.5% of controls; 68.2% of males and 51.6% of females with osteoarthritis knee had abnormal fasting plasma glucose. Among the cases, 27.3% were diabetic. We did not find any association between dysglycæmia and OA knee.

**Lipid Profile Abnormalities**

Raised total cholesterol (> 200 mg/dL) was present in 62% of cases and 57.5% of controls. Raised triglycerides (> 150 mg/dL) was seen in 26% of cases and 23.8% of controls. Reduced HDL was seen in 54.7% of cases and 50% of controls. LDL was high (>160mg/dl) in 32% of cases and 23.75% of controls. There was no association between dyslipidaemia and OA knee in our study.

**The Anthropometric Abnormalities Detected were:**

Increased waist circumference was observed in 86.7% of cases (50% in males and 93% in females) and 87.5% of controls. Abdominal obesity was more common in females among both cases and controls.

The mean BMI was 28.55 (25.01 in males and 29.16 in females) amongst the cases and 29.71 amongst the controls.

**Gender Distribution of Metabolic Syndrome among Cases and Controls**

Metabolic syndrome was present in 77.3% of female cases compared to 40.9% of male cases. The association of metabolic syndrome with knee osteoarthritis in females was statistically significant with ‘p’ value of 0.000. (Table 2 and Figure 3).
DISCUSSION

Osteoarthritis of knee is one of the most common musculoskeletal conditions. In our study, we found a statistically significant association between osteoarthritis of knee and metabolic syndrome. The association was found more significant in females. Our results are very close to the findings of the following studies.

Engstrom et al.26 found that the presence of metabolic syndrome correlated significantly with osteoarthritis of the knees. However, this relationship ceased to exist after adjustment for BMI. In the Japanese study by Ryo Inoue et al.,23 the prevalence rates of both metabolic syndrome and knee OA tended to increase with age. Although, there was no association between metabolic syndrome and knee OA in males, the presence of knee OA was significantly associated with that of metabolic syndrome in females. In the US National HANES (NHANES III; 1988–1994) study, metabolic syndrome was more prevalent in persons with OA from among > 7,000 adults.24 In the Michigan Bone Health and Metabolism Study, in obese women the presence of two or more cardiometabolic risk factors was associated with more reports of persistent knee pain over the previous 3 years.25 In the Japanese Research into Osteoarthritis Against Disability (ROAD) study, the odds of OA increased with the presence of each additional component of MetS. Furthermore, in a Russian study in 1,350 individuals with OA 62.56% were also diagnosed with MetS.26

Our study also found out an association between hypertension and OA knee. The association of metabolic syndrome with OA knee indicates the high risk of cardiovascular diseases in these patients. As OA knee is a common problem encountered in rehabilitation medicine, further longitudinal studies are required to establish a causal association between OA knee and metabolic syndrome. Also, all patients with OA knee should be evaluated in detail to identify underlying metabolic abnormalities and treated accordingly, so that we can reduce future disabilities especially those related to cardiovascular diseases.

CONCLUSION

1. Metabolic syndrome was more common among persons with osteoarthritis of knee and the association was statistically significant.  
2. Association of metabolic syndrome with osteoarthritis of knee was more in females.  
3. Among the metabolic profile abnormalities, there was significant association of hypertension with osteoarthritis.  
4. The association between hypertension and osteoarthritis of knee was also more among females.  
5. All patients with OA knee should be evaluated to identify underlying metabolic abnormalities and treated accordingly, so that we can reduce future disabilities related to cardiovascular diseases.

Limitations of the Study

1. The sample size was small, number of male subpopulation smaller.  
2. Due to practical constraints in making a patient without a knee pain to undergo metabolic syndrome screening, the number of participants in the control group was low. So the chances of bias due to confounding factors were high.  
3. It was a hospital-based study, and hence may not be representative of general population.
