ABSTRACT

BACKGROUND
Rh-D haemolytic disease of foetus and newborn (HDFN) is an ailment in which lifespan of infant’s erythrocytes were shortened by the action of placentally transferred maternal anti-D specific for inherited paternal red cell antigens. The aim of this study is to describe the immunological profile of Rh-D HDFN.

Settings and Design- This was a descriptive study conducted among newborn with Rh-D HDFN. Setting was Depts. of Transfusion Medicine and Paediatrics in Govt. Medical College, Trivandrum.

MATERIALS AND METHODS
Enrolment of newborn was done according to the inclusion criteria. Demographic details, maternal history, bilirubin and haemoglobin levels were noted. Blood group and peak antibody level of mother were recorded. Direct antiglobulin test, blood grouping and elution was performed in infant.

Statistical Analysis- All statistical data were analysed using SPSS software version 16.

RESULTS
In mothers of infants with Rh-D HDFN, 3 (6.8%) had a titre of 2, 6 (13.6%) had a titre of 4, 3 (6.8%) had a titre of 8, 2 (4.6%) had a titre of 16, 3 (6.8%) had a titre of 32, 7 (15.9%) had a titre of 64, 6 (13.6%) had a titre of 128, 7 (15.9%) had a titre of 256, 5 (11.4%) had a titre of 512 and 2 (4.6%) had titres of 1024. While considering DAT positivity in infants with Rh-D HDFN, 1 (2.3%) fell in grade 1, 33 (75%) in grade 2, 6 (13.6%) in grade 3 and 4 (9.1%) in grade 4 categories.

CONCLUSION
High titres of anti-D ranging from 128 - 1024 were observed in 45.5% of mothers of infants with Rh-D HDFN. While considering DAT positivity in infants with Rh-D HDFN, majority fell in grade 1 and 2 categories.

KEYWORDS
Haemolytic Disease of Foetus and Newborn, Hyperbilirubinaemia, Antibody, Rh-D, Direct Antiglobulin Test, Elution.

BACKGROUND
Rh-D haemolytic disease of foetus and newborn (HDFN) is an ailment in which lifespan of infant’s erythrocytes were shortened by the action of placentally transferred maternal anti-D specific for inherited paternal red cell antigens.¹

Programs for ABO grouping, Rh typing, antenatal antibody screening and other advanced therapeutic modalities which focused on foetuses and neonates at risk had reduced the burden of disease in developed nations.²

Implementation of same had posed both organisational and economic challenges in countries with a low human development index.³

Even though there were 160 blood banks in Kerala, routine antenatal antibody screening was performed only in a very few centres. Hence, assessing the immunological profile of Rh-D HDFN was undertaken in this study.

MATERIALS AND METHODS
This was a descriptive study done in 44 neonates who had Rh-D HDFN. Study setting was Dept. of Transfusion Medicine and Neonatology division of Sree Avittom Thirunal Hospital for women and children in Govt. Medical College, Trivandrum.

As a policy of institution, newborn with increased bilirubin levels and those born to mothers with antenatal antibody screen positivity were kept under observation. Those neonates fulfilling the inclusion criteria were enrolled in this research. Study was finished in 18 months, the timeframe from 01-03-2012 to 30-08-2013.
Inclusion Criteria for Rh-D HDFN
1. Maternal antibody screening was positive for anti-D and presence of D antigen in newborn.
2. No ABO incompatibility between mother and neonate.
3. Positive DAT and elution in neonate.
4. Hyperbilirubinaemia within first 24 hours of birth.
5. No other diagnosed cause for increased bilirubin.

Exclusion Criteria
Features of HDFN concomitantly with any condition attributed to hyperbilirubinaemia.

Details such as name, age, IP no., bed no. and addresses were recorded. Maternal details such as parity and blood group were noted. Hyperbilirubinaemia was classified according to chart provided by American Academy of Paediatricians (AAP). The disease was graded as mild, moderate, severe and very severe as described by Andrew et al. (Mild-Grade 0; Hb > 12.5 g/dL, no transfusions; Moderate-Grade 1: Hb > 12.5 g/dL + top-up or exchange transfusion, Severe-Grade 2: Hb < 12.5 g/dL + exchange transfusion, Very severe-Grade 3: Intra-uterine transfusions and/or Hb < 10.0 g/dL ± exchange transfusions or foetal death). Anemia was graded according to description in Wintrobe’s Haematology6 (No- Hb ≥ 17 g%, Mild-Hb 14 – 17 g%, Moderate-Hb 12 – 14 g%, Severe-Hb < 12 g%).

Treatment was graded as described in Wintrobe’s Haematology6 (Grade 0- no treatment, Grade 1- phototherapy alone, Grade 2- phototherapy and IVIG, Grade 3-phototherapy, IVIG and single exchange transfusion, Grade 4-phototherapy, IVIG and multiple exchange transfusions) haemoglobin levels, disease severity and intensity of treatment were recorded.

10 mL venous blood was collected from mothers. Blood group and presence of antibody was confirmed in the drawn sample. Peak antibody titre value performed during antenatal period was noted down. Immuno-haematological investigations was done in 5 mL of umbilical cord blood collected during delivery was used for performing.

ABO grouping was done by test tube method. Forward grouping was done using monoclonal anti-A, anti-B and anti-AB by tulip diagnostica.

If necessary, serum grouping was performed using pooled A1, B and O group cells. After centrifugation, either haemolysis or agglutination in tests with red cells and serum constituted positive test results. Red cell test results were compared with those obtained in serum tests.

Determination of Rh-D type of red cells was done with monoclonal IgG anti-D by tube test.

After centrifugation, agglutination in the test sample combined with agglutination in positive control and a smooth suspension in negative control tube indicated that the red cells under investigation were D-positive.

A smooth suspension of red cells in the test sample and negative control tube with positivity in positive control is a negative test result. Those samples were tested further for the presence of weak D-antigen by an indirect antiglobulin procedure.

Monoclonal IgG anti-D and polyclonal antihuman globulin reagents were used for weak-D tests. Agglutination in the anti-D tube and none in the control tube constituted a positive test result.

Absence of agglutination in the anti-D tube and control tube in D negative samples were confirmed by addition of IgG coated red cells.

Gel cards with antihuman globulin reagent were used for indirect antiglobulin tests. IAT was done by adding 50 µL of red cells suspended in LISS solution and 25 µL of serum to microtubes. It was incubated for 15 mts at 37°C and centrifuged for 10 mts. Agglutinated cells which formed a red line on the surface of the gel or agglutinates dispersed in the gel indicated a positive result. Compact button of cells on the bottom of the microtube indicated a negative test.

A positive reaction in antibody screening test with 3 cell panel indicated the presence of irregular antibodies. Identification tests were done on those samples using 11 cell panel.

Direct antiglobulin test was done using LISS Coombs gel card; 50 µL of the red cell suspension was added to the appropriate microtube and it was centrifuged for 10 minutes.

Results were read and graded. (+) - solid band of red cells on the top of the gel column, 3- agglutinated red cells in the upper half of the gel column, 2- red cell agglutinates through the length of the column, 1- red cell agglutinates mainly in the lower half of the gel column with some unagglutinated red cells pelleted at the bottom, Negative- a pellet at the bottom and no agglutinates in the matrix of the gel column). A positive result indicated that the red cells were sensitised with IgG antibodies and/or complement. Presence of antibody was confirmed by elution tests.

DAT positive red cells in Rh HDFN were eluted using glycine-HCl/EDTA eluting solution. If eluate was reactive and final wash supernate was non-reactive, then eluate reactions were valid. If eluate was non-reactive and final wash supernate was nonreactive, then no antibody was eluted.

Ethics
Study was approved by human ethical committee and review board of institution. Parents of all study subjects were counselled separately about the nature and effects of the study and a written consent was obtained from them.

Statistical Analysis
Statistical data analysis was done in SPSS software version 16. Expression of continuous variables was as mean ± standard deviation. Expression of qualitative data was as frequencies and percentages. Correlation between variables was done using spearman correlation test. All ‘p’ values were two tailed. P value < 0.05 were considered statistically significant.

RESULTS
In mothers of infants with Rh-D HDFN, 3 (6.8%) had a titre of 2; 6 (13.6%) had a titre of 4, 3 (6.8%) had a titre of 8, 2 (4.6%) had a titre of 16, 3 (6.8%) had a titre of 32, 7 (15.9%) had a titre of 64, 6 (13.6%) had a titre of 128, 7 (15.9%) had a titre of 256, 5 (11.4%) had a titre of 512 and 2 (4.6%) had titres of 1024. While considering DAT positivity in infants with Rh-D HDFN, 1 (2.3%) fell in grade 1, 33 (75%) in grade 2; 6 (13.6%) in grade 3 and 4 (9.1%) in grade 4 categories.
Grades of DAT | Frequency | Percentage |
--- | --- | --- |
Negative | 0 | 0.0 |
1 | 1 | 2.3 |
2 | 33 | 75.0 |
3 | 6 | 13.6 |
4 | 4 | 9.1 |
Total | 44 | 100.0 |

Table 4. Parity of Mothers of Infants with Rh-D HDFN

In Rh-D HDFN parity was not significantly correlated with grades of DAT and titres of antibody in mothers. Correlation was significant at the 0.01 level.

DISCUSSION

44 neonates admitted in newborn nursery of Govt. Medical College, Thiruvananthapuram with Rh-D HDFN was studied.

In immune-mediated HDFN, lifespan of foetal or neonatal erythrocytes are shortened by placentally transferred maternal antibodies.¹

Bjarte G. Solheim opined that immunisation had occurred when the foetal red cells were traversed through the placenta into maternal circulation or when the antigens were transferred by previous transfusions.⁷ Only maternal IgG antibodies could cross the placenta.⁷

Harvey Klein and David Anstee had opined that the Rh antigens were present only on red cells; hence, D immunisation evolved in D negative subjects either after injection of D positive red cells or following transplacental haemorrhage from a D positive foetus.⁸

Mollison et al observed that the D antigen was 20 times more immunogenic than C, the next most potent Rh antigen.⁹ When D negative infants were transfused with one or more units of D positive red cells, 80% - 90% developed anti-D within two months.¹⁰

Incidence of D immunisation depended on the dose of D positive RBCs, 15% after 1 mL, 33% after 40 mL and 65% to 70% after 250 mL.¹¹ Secondary immune responses had occurred after exposure of 0.1 mL of Rh positive red cells.¹²

Hartmann had opined that approximately 1% of D negative women with no history of previous transfusion were found to be sensitised at the end of their first D positive pregnancy.¹³

But in this research no mother was without history of transfusion or pregnancy was sensitised. Bishop GJ and Krieger VI observed that when anti-D was developed during first pregnancy it was most commonly first detectable in the last few weeks of pregnancy or at the time of delivery.¹⁴

Krevans et al observed that foetal red cells could be detected in greater proportion of women towards the end of pregnancy than in the earlier stages.¹⁵

Frequency with which foetal red cells could be identified in the maternal circulation varied widely in various studies, i.e. 0.40% - 5.8% at 28 - 30 weeks and 1.84% - 7.0% at 30 - 39 weeks.¹⁶ Woodrow and Finn demonstrated a relationship between the number of foetal red cells in maternal circulation at the time of delivery and the chance of anti-D appearance thereafter.¹⁷

In an analysis by Boorman et al, the titre of anti-D was increased after delivery and a peak was reached by 1 - 3 weeks.¹⁸ Six months after the birth of first D positive ABO compatible infant, incidence of anti-D in D negative women ranged from 4.3% to 9.0%.¹⁹ R² infants were more effective in sensitising their mothers to D antigen.²⁰

TPH was relatively common during normal delivery and a study by Woodrow showed that 65% of TPH occurred during delivery itself.²¹ In three investigations, estimates of the extent of TPH were similar: 1% of women had 3.0 mL or more and 0.3% had 10 mL or more of foetal red cells in their circulation at the time of delivery.²²,²³,²⁴

Allowing free drain of placental blood immediately after cord clamping and infant separation had substantially reduced the incidence and magnitude of TPH.²⁵ As per the research of Finn R et al caesarean section and manual removal of placenta were associated with five- to ten-fold increases in incidence and degree of TPH.²⁶
Li et al found out that foetal distress during labour was significantly high when TPH was 5 mL or more.27 Two other routes through which foetal red cells could reach mother’s peritoneal cavity and thence into maternal circulation were spillage of foetal blood into uterine cavity or fallopian tubes and hysterotomy or caesarean section.28 The protection observed in ABO incompatible situations was due to rapid clearance of A or B red cells, which prevented immunologic processing of Rh antigens.29 Murray et al noticed that group A incompatibility between infant and mother gave 90% and group B incompatibility gave 55% protection against D immunisation.30 Some D-negative infants born to D-positive mothers might develop anti-D within the first 6 months of life.31,32

Zhu X, Meng had opined that placental transport was an active process dependent on interaction between maternal IgG and Fc receptors in synciotrophoblast.33 The transfer of IgG took place only from mother to foetus and not in the reverse direction.34 Even though only small amounts of IgG were transferred in first 12 weeks of gestation, DAT on foetal D positive red cells might be positive as early as 6 - 10 weeks.35

Hay FC et al found out that IgG1 levels rose at an earlier stage of gestation than IgG3 levels.36 Although, foetal to maternal ratios of all four IgG subclasses were found to be similar in cord serum by Morell and co-workers, others found a relative deficiency of IgG2.37

The relative concentration of IgG1 in foetal serum compared with maternal serum was 1.77.38 Fcγ receptors in placental tissue were bound to IgG1 with a higher affinity than IgG3.39

In infants with passively acquired anti-D, the antibody titre declined with a T1/2 of 2 - 3 weeks and DAT remained positive for 3 months.34

Natvig et al reported that immunogenic Rh antibodies were mainly IgG1 followed by IgG3.40 Schur et al opined that IgG1 levels increased at an earlier gestational age than IgG3, whereas IgG2 coated red cells were rapidly cleared from circulation as compared to IgG1 coated cells.41 As per Hughes Jones opinion, Rh antibodies did not activate complement completely.42

Among 44 D negative mothers in this research, high titres ranging from 128 - 1024 were observed in 45.5%. In Rh-D HDFN titre of maternal antibody was positively correlated with risk related to peak bilirubin levels, severity of disease and intensity of treatment and negatively correlated with cord blood haemoglobin levels, while it was not correlated with grades of DAT.

Just as with our study another one conducted by Shaiji in the same setting showed significant correlation between antibody titre in mothers of infants with Rh-D HDFN and umbilical cord bilirubin levels.43 ACOG has opined that critical titre of anti-D in maternal sera was usually 16 or 32 in the antihuman globulin phase.44

According to Alexander et al, a 4-fold increase in antibody titre was typically considered as a significant change which required foetal evaluation.45 Bowman opined that Rh antibody titration could predict the foetuses at risk, but not the severity of erythroblastosis.46 But Bowell et al demonstrated a clear relationship between increasing anti-D titre and the chance for a severely affected infant.47

A low value of antibody concentration estimated using an auto-analyser had indicated that the infant would be mildly affected or unaffected and an increase in anti-D concentration indicated increasing severity of haemolytic disease.48 HDFN was less severe when only IgG3 anti-D was present as compared to IgG1 alone or IgG1 and IgG3 together.49 Parinaud et al observed that when both IgG1 and IgG3 were present, IgG1 was usually preponderant and most severe disease was correlated with IgG1 levels.50

Distribution according to grades of DAT positivity in infants with Rh-D HDFN in present analysis had revealed a highest sharing in grade-2 reaction group. In our study, 22.7% of infants had grade-3 or grade-4 DAT.

Increasing grades of DAT were not at all correlated with severity of disease, intensity of treatment, risk related to peak bilirubin levels and cord blood haemoglobin values. Similarly, a research accomplished by Shaiji in same setting found no correlation between grades of DAT and intensity of treatment in Rh-D HDFN.43

Likewise, Mollison and Cuthbush opined that no correlation between DAT and severity of the disease.51 Harvey Klein and David Anstee observed that in Rh-D haemolytic disease, infants might have a strongly positive DAT without showing any clinical signs of disease.52

Bjarle G. Solheim and Morten Grön observed that some D positive infants with a positive DAT might show no signs of red cell destruction.3 Bowman opined that several factors such as Rh antibody binding constant, amount of D antigen on red cell membrane, ability of foetus to maintain a reasonable haemoglobin level, etc. had influenced the severity of erythroblastosis.46

In Rh-D haemolytic disease, infants might have a strongly positive DAT without showing any clinical signs of disease.52 The research was a descriptive one with a limited data. Hence, there were some limitations in assessing correlation between variables. For procuring more information long-term analytical studies have to be undertaken.

**CONCLUSION**

1. High titres of anti-D ranging from 128 - 1024 were observed in 45.5% of mothers of infants with Rh-D HDFN.
2. Titre of maternal anti-D was positively correlated with risk related to peak bilirubin levels, severity of disease and intensity of treatment and negatively correlated with cord blood haemoglobin levels.
3. While considering DAT positivity in infants with Rh-D HDFN, majority fell in grade 1 and 2 categories.
4. Increasing grades of DAT were not correlated with severity of disease, intensity of treatment, risk related to peak bilirubin levels and cord blood haemoglobin values.
