ABSTRACT

BACKGROUND

Leptospirosis is a bacterial infectious disease that affects humans and animals. It is caused by pathogenic spirochetes of the genus Leptospira. It is a specific zoonotic disease with worldwide distribution with a much greater incidence in tropical countries like India. In West Bengal, especially in Kolkata, there is high average rainfall with water holding capacity of soil. Also, there is a huge natural population of rodents and stray dogs which serve as the carrier of the disease. The sanitary arrangements for the roadside slaughtering houses are very poor. In the rainy season, parts of the city remain waterlogged.

The above points are the sole reasons for the cases of leptospirosis in the city of Kolkata. There were considerable good number of cases from the surrounding areas.

MATERIALS AND METHODS

The study was conducted between 2009 to 2017 in a Medical College and Hospital, Kolkata. Samples were collected from clinically suspected cases, with history of possible exposure, in the rainy seasons and included the same in our study for testing. We got a total of 42 suspected cases during the eight-year study period. Cases were mostly from Kolkata, suburbs, North and South 24 Parganas and Midnapore. Microscopic agglutination test (MAT) following standard procedures was used. 7 Reference strains belonging to 12 serogroups were included in the MAT panel as antigens.

RESULTS

Of the 42 sera tested, 34 (30.4%) were positive for IgM antibodies against Leptospira, and 32 of these were positive by latex agglutination method. Also, MAT was positive in thirty of these thirty-four positive patients. Antibodies were found against several serogroups (Australis 1:100; Bataviae 1:200; Canicola 1:20; Copenhageni 1:400; Sejroe 1:800; Ballum 1:100; Icterohaemorrhagiae 1:100; Pyrogenes 1:800). But antibodies of multiple serogroups were not found in a single specimen.

CONCLUSION

Current methods for the direct detection of Leptospirases are either slow or of limited reliability so that serology is often the most appropriate diagnostic method. Treatment with effective antibiotics should be initiated as soon as the diagnosis of leptospirosis is suspected and preferably before the fifth day after the onset of illness. The benefit of antibiotics after the fifth day of the disease is controversial. However, most clinicians treat with antibiotics regardless of the date of onset of the illness. These were done in all of these cases and there was no death among the four positive cases.

BACKGROUND

Leptospirosis is a bacterial infectious disease that affects humans and animals. It is caused by pathogenic spirochetes of the genus Leptospira. It is a specific zoonotic disease with worldwide distribution with a much greater incidence in tropical countries like India. It is a very common zoonosis in the world associated with rodents in poor sanitation areas in tropical countries like India. It is a very common zoonosis in worldwide distribution with a much greater incidence in human and animals. It is caused by pathogenic Leptospires. It is a specific zoonotic disease with worldwide distribution with a much greater incidence in tropical countries like India. In West Bengal, especially in Kolkata, there is high average rainfall with water holding capacity of soil. Also, there is a huge natural population of rodents and stray dogs which serve as the carrier of the disease. The sanitary arrangements for the roadside slaughtering houses are very poor. In the rainy season, parts of the city remain waterlogged.

The above points are the sole reasons for the cases of leptospirosis in the city of Kolkata. There were considerable good number of cases from the surrounding areas.
haemorrhage Syndrome (LPHS), is considered by some authors as a form of leptospirosis distinct from Weil's disease because pulmonary manifestations are found to occur solely without any kind of hepatic or renal manifestations. The mortality rate of leptospirosis is high, reaching 2.5\% to 16.4\%. At the age of over 50 years mortality rate can be up to 56\%. When leptospirosis patient is accompanied by a yellow lining of the eye indicating damage to the liver tissues, the risk of mortality will be higher. Several publications reported mortality rates between 3\%-54\% depending on the infected organ system. Initially in China and Korea, it was thought that only one particular serotype is showing pulmonary manifestation but later several species and serovars of Leptospira have been shown to cause pulmonary haemorrhage. The haemorrhagic manifestations are the main clinical identification features in thrombocytopenic cases. Some authors described that thrombocytopenia as significant predictor for renal failure in leptospirosis patients. Neurological signs and symptoms are seen in some patients, their clinical feature being stiff neck with altered sensorium. In the Indian case scenario, total case fatality ratio in Chowdry's case series was 13.2 percent. There were considerable good number of cases from the surrounding areas. So a study was planned from November 2009 to September 2017 to inspect the real case scenario of leptospirosis in the surrounding areas. The weather conditions, waterlogging and presence of roadside meat shops considerably create an ideal environment for the spread of the disease. There were also few clinicians who inspected and suggested for evaluation of some patients for leptospirosis which was another contributing factor for planning this study.

MATERIALS AND METHODS
The study was conducted between 2009 to 2017 in a Medical College and Hospital, Kolkata. Samples were collected from clinically suspected cases, with history of possible exposure, in the rainy seasons and included the same in our study for testing. We got a total of 42 suspected cases during the eight-year study period. Cases were mostly from Kolkata, suburbs, North and South 24 Parganas and Midnapore. It is a retrospective study based on secondary data from records.

Laboratory Procedure
Serum was separated from blood samples and stored at –20°C until it was processed. Sera samples were tested for the presence of anti-Leptospiral antibodies using Microscopic agglutination test (MAT) following standard procedures. Serum was separated from blood samples and stored at –20°C until it was processed. Sera samples were tested for the presence of anti-Leptospiral antibodies using Microscopic agglutination test (MAT) following standard procedures. Serum was separated from blood samples and stored at –20°C until it was processed. Sera samples were tested for the presence of anti-Leptospiral antibodies using Microscopic agglutination test (MAT) following standard procedures. 7 reference strains belonging to 12 serogroups were included in MAT panel as antigens. These include Australs (serovar Australis, strain Ballico), Autumnalis (serovar Autumnalis, strain Rachmat), Bataviae (serovar Bataviae, strain Swart), Canicola (serovar Canicola, strain Hond Utrecht IV), Grippotyphosa (serovar Grippotyphosa, strain Moskva V), Icterohaemorrhagiae (Serovar Icterohaemorrhagiae, strain RGA), Javanica (Serovar Poi, strain Poi), Pomona (serovar Pomona, strain Pomona), Sejroe (serovar Hardjo, strain Hardjoprajitno), Ballum (serovar Ballum, strain Mus 127), Cynopteri (Serovar Cynopteri, strain 3522C) and Pyrogenes (Serovar Pyrogenes, strain Salinem). The antigens used were 5-7 days’ old autoagglutination-free cultures grown in Ellinghausen-McCullough-Johnson-Harris (EMJH) medium (Difco, Sparks, MD) with approximately 1×10⁸ to 2×10⁸ organisms/mL. MAT was done at doubling dilutions starting from 1 in 25. Positive samples were titrated up to end titres. A titre of 1 in 50 or more against any of the serovars was considered as evidence of Leptospiral infection.

RESULTS
Of the 112 sera tested, 34 (30.4\%) were positive for IgM antibodies against Leptospira, and 32 of these were positive by latex agglutination method. Also, MAT was positive in thirty of these thirty four positive patients. In this patient, antibodies were found against several serogroups (Australis 1:100; Bataviae 1:200; Canicola 1:200; Copenhageni 1:400; Sejroe 1:800; Ballum 1:100; Icterohaemorrhagiae 1:100; Pyrogenes 1:800). But antibodies of multiple serogroups was not found in a single specimen. In one participant without clinical symptoms, seropositivity for serogroups Icterohaemorrhagiae/Copenhageni 1:100 were found. Clinical disease was mild in most cases with fever most frequently reported (100%) followed by headache (23/34) and muscle pain (34/34). Diarrhoea and renal impairment were reported from single patients, respectively. Jaundice, pulmonary haemorrhage, meningoencephalitis, or other severe manifestations of leptospirosis were not reported. No deaths were reported. Thirty three of the thirty-four patients required hospitalisation.

DISCUSSION
Leptospirosis occurs in the form of seasonal post-monsoon outbreaks with considerable mortality. Leptospires have good affinity to areas where heavy rainfall results in waterlogging of the land. Human populations residing in such environment are at higher risk of acquiring Leptospiro infection. The majority of the affected population belongs to the agriculture community. The present study has been undertaken as a retrospective study. There was 30.4\% positivity observed among suspected cases. Several different authors have described outbreak of Leptospiro in different parts of our country as well as the world. Sethi et al from North India reported 11.7\% occurrence (2004-2008) in 2004 and 20.5 \% in 2008. A total of 215 number of cases has been reported from South India from the city of Coimbatore, TamilNadu (2007 - 2009), 130 cases have been reported from Trivandrum, Kerala in 2005. A huge number of cases are getting reported from Andaman Islands, where this is an
endemic disease. In our positive cases also, one patient has given the history of travelling to Andaman. Mostly waterlogged conditions of Kolkata and Road side butcher houses can also be attributed to the Seropositive cases. So the above results clearly justify that the study was planned at right time and the results also signify the same.

CONCLUSION
Current methods for the direct detection of leptospires are either slow or of limited reliability so that serology is often the most appropriate diagnostic method. Moreover, in practice, patients often seek medical care or are admitted in hospitals when they have already been ill for a sufficiently long time to have produced detectable antibodies. Several types of antibody detection assays have been developed for early diagnosis of leptospirosis. These include the haemolytic test, indirect haemagglutination assay, indirect immunofluorescence, indirect IgM ELISA, IgM dot-ELISA, immobilised antigen dipstick and lateral flow assays. While these methods are much simpler than MAT, they still need a lag period after infection before antibodies become detectable. One should be careful while interpreting the test results due to varying sensitivity and specificity of the test method. The ELISA tests have been the most readily applicable for the rapid detection and diagnosis of leptospirosis. Several published studies have compared and evaluated a range of commercially available assays. Treatment with effective antibiotics should be initiated as soon as the diagnosis of leptospirosis is suspected and preferably before the fifth day after the onset of illness. The benefit of antibiotics after the fifth day of the disease is controversial. However, most clinicians treat with antibiotics regardless of the date of onset of the illness. These was done in all of these cases and there was no death among the four positive cases.
